Handbook of Paleoanthropology
We dedicate these volumes to our long-time colleagues Hartmut Rothe and Theodoros Pitsios in appreciation of their friendship and unique contributions to primatology and paleoanthropology.
Preface to the Series

Palaeoanthropology is perhaps the most multidisciplinary of all the sciences. Any complete account of the evolution and of the cultural and biological contexts of *Homo sapiens* must combine information from geology, paleoecology, primatology, evolutionary biology and a host of other fields. Above all, historical information garnered from the fossil record needs to be combined with, and interpreted in the light of, what we know of the living world. In these volumes we have brought together contributions by a variety of leading specialists that reflect the broad spectrum of modern paleoanthropology, in an attempt to provide a resource that we hope will be useful to professionals and students alike.

Volume I of this three-volume Handbook deals with principles, methods, and approaches. In recent years enormous advances have been made in such areas as phylogenetic analysis, evolutionary theory and philosophy, paleoecology, and dating methods. The contributions aim to present the state of the art in these and other relevant fields, as well as to furnish succinct introductions to them and to reflect the many ways in which they interact. Human beings are primates, and Volume II is devoted to primate origins, evolution, behavior, and adaptive variety. In this compilation the emphasis is on the integration of fossil data with the vast amount that is now known of the behavior and ecology of living primates in natural environments. The third and final volume deals directly with the fossil and molecular evidence for the evolution of *Homo sapiens* and its fossil relatives (the family Hominidae or subfamily Homininae, according to taste, a matter that we have left to each individual contributor). Paleoanthropology is a pluralistic and actively developing field in which much remains to be settled, and we have not tried to impose any uniformity of viewpoint on our authors. Instead, while maintaining an emphasis on the data, we have encouraged them to express their individual interpretations rather than to cover all possible points of view. This has inevitably led to a certain degree of heterogeneity of opinion between the covers of this Handbook; but we believe that this is the best way of reflecting the excitement and momentum of the field and that it is best for the reader to be left to reach his or her own conclusions. Science is, after all, a process rather than a static product, and one of our primary aims here is to reflect the ongoing dynamism of that process in paleoanthropology.

We thank all of the contributors to these volumes for their participation. Some initially responded enthusiastically while others needed convincing about the basic strategy of the Handbook, but all responded marvellously to the
particular needs of a corporate effort such as this one. We are particularly grateful to those authors who responded at short notice to needs that became apparent only as the project progressed. This series was conceived in collaboration with Prof. Hartmut Rothe of the University of Göttingen, who was later forced to withdraw for reasons beyond his control. We thank him most warmly for his creativity in the conceptual stages and for his subsequent moral support. The laborious process of putting together the volumes could not have been accomplished without the cheerful help of Thorolf Hardt, whose active involvement was indispensable throughout.

This project could never have come to fruition without the enthusiastic support of Dr. Dieter Czeschlik, editor life sciences at Springer Publishing, and the efficient assistance of Mrs. Ursula Gramm. We express our deep gratitude to Mrs. Susanne Friedrichsen and Mrs. Caroline Simpson, who showed both care and commitment during the phases of copyediting and product development. The continuous cooperation and dialogue with them and their professionalism gave us the courage to see the project through. Further thanks go to Mrs. Sandra Fabiani and her colleagues at Springer Publishing, who prepared the eReference. Ms. Nitya Swaruba, compositor at SPi Technologies, deserves warm thanks for her efficient help, and finally our gratitude goes in addition to Britta Hardt, Peter Menke and Monika Sandführ, who also rendered much valuable assistance.

Mainz and New York City
November, 2006
Table of Contents

Volume 1

1 Historical Overview of Paleoanthropological Research ............... 1
   Winfried Henke

2 Evolutionary Theory in Philosophical Focus ....................... 57
   Philippe Huneman

3 The Ontogeny–Phylogeny Nexus in a Nutshell: Implications for
   Primatology and Paleoanthropology ............................ 103
   Peter R. Menke

4 Principles of Taxonomy and Classification: Current Procedures
   for Naming and Classifying Organisms .......................... 141
   Michael Ohl

5 Quantitative Approaches to Phylogenetics .......................... 167
   Kaila E. Folinsbee · David C. Evans · Jörg Fröbisch · Linda A. Tsuji ·
   Daniel R. Brooks

6 Homology: A Philosophical and Biological Perspective ............. 217
   Olivier Rieppel

7 Taphonomic and Diagenetic Processes .............................. 241
   Gisela Grupe

8 Archeology .................................................. 261
   Miriam N. Haidle

9 Contribution of Stable Light Isotopes to Paleoenvironmental
   Reconstruction .................................................. 289
   Julia Lee-Thorp · Matt Sponheimer

10 Chronometric Methods in Paleoanthropology ..................... 311
    Günther A. Wagner

Winfried Henke is currently Professor of Anthropology at the Johannes Gutenberg University of Mainz. He was born in 1944 in Ludwigshorst/Pomerania, Germany, and studied biology, anthropology and geosciences in Kiel and Braunschweig. He received his Ph.D. from the University of Kiel in 1971, his thesis focusing on a prehistoric anthropological topic. In 1990 he habilitated with a monograph on the “Anthropology of Early Paleolithics and Mesolithics” at the University of Mainz.

Research activities in various countries (Iceland, Israel, Jordan, US, Greece) and extensive teaching assignments in the Erasmus exchange program at numerous European Universities followed. From 1996 to 2004, he acted as anthropology referee for the German Research Foundation (DFG). He served at the advisory boards of many scientific journals, and was advisory consultant to museums, e.g. the Neanderthal Museum (Mettmann, Germany). In 2006 he was awarded with the honorary doctorate of the National and Kapodistrian University of Athens and is an elected member of the German Academy of
Sciences Leopoldina. Areas of research and teaching: paleoanthropology, primatology, prehistoric anthropology, comparative morphology, systematics, demography and sociobiology.

He has published approximately 180 original papers in scientific journals and anthologies, and over 600 book reviews. He is author, co-author (together with H. Rothe) and editor of several books, including such standard works as “Paläoanthropologie” and “Stammesgeschichte des Menschen” (published at Springer-Verlag).

**Ian Tattersall** is currently Curator in the Division of Anthropology of the American Museum of Natural History in New York City. Born in England and raised in East Africa, he has carried out both primatological and paleontological fieldwork in countries as diverse as Madagascar, Vietnam, Surinam, Yemen and Mauritius. Trained in archeology and anthropology at Cambridge, and in geology and vertebrate paleontology at Yale, Tattersall has concentrated his research since the 1960s in two main areas: the analysis of the human fossil record and its integration with evolutionary theory, and the study of the ecology and systematics of the lemurs of Madagascar. Tattersall is also a prominent interpreter of human paleontology to the public, with several trade books to his credit, among them *The Monkey in the Mirror* (2002), *Extinct Humans* (with Jeffrey Schwartz, 2000), *Becoming Human: Evolution and Human Uniqueness* (1998) and *The Last Neanderthal: The Rise, Success and Mysterious Extinction of Our Closest Human Relatives* (1995; rev. 1999) as well as several articles in *Scientific American* and the co-editorship of the definitive *Encyclopedia of Human Evolution and Prehistory*. He lectures widely, and, as curator, has also been responsible for several major exhibits at the American Museum of Natural History, including *Ancestors: Four Million Years of Humanity* (1984); *Dark Caves, Bright Visions: Life In Ice Age Europe* (1986); *Madagascar: Island of the Ancestors* (1989); *The First Europeans: Treasures from the Hills of Atapuerca* (2003); and the highly acclaimed *Hall of Human Biology and Evolution* (1993).

**Thorolf Hardt** graduated in biology and is currently a PhD student at the Institute of Anthropology, University of Mainz. He was born in 1973 in Neustadt (RhP/Germany) and studied anthropology, paleontology and zoology in Kiel and Mainz. At present his research activities are focused on Geometric Morphometrics, functional morphology and evolutionary biology in Primates.

1 Historical Overview of Paleoanthropological Research

Winfried Henke

Abstract

This chapter provides a comprehensive scientific historical overview on paleoanthropology as a multifaceted biological discipline. A terse compendium on pre-Darwinian theories of evolution is followed by a historical report of the paradigmatic change by Darwin’s perspective on life processes from a teleological to a teleonomic view. Focusing on the fossil discoveries in Europe and later on in Asia and Africa and the different methodological approaches, it becomes obvious that as opposed to other biological disciplines, paleoanthropology remained until post-World War II first and foremost a narrative discipline, apart from the mainstream of biological thinking. Paleoanthropology kept this “iridescent image” in the public opinion until now, wrongly, as is proven. It is shown that since Washburn brought up an innovative conceptual outline on physical anthropology in 1951, there arose a methodological change in the understanding of human evolution as a self-organizing process focusing on the structural and functional adaptations within the order Primates. The anthropological subdiscipline paleoanthropology profited tremendously from this new approach—albeit with some delay. Current paleoanthropological research does not only ask what our forerunners looked like and when, where, and how they evolved but also specifically seeks to explain the processes of radiation, diversification, and variability by concise hypothesis testing. We have to reconstruct the ecological niche of the fossil humans to define the determinants that caused adaptation in human evolution, a process sometimes defined as hominization, including our biogenetic and tradigenetic evolution.

1.1 Introduction

1.1.1 Historical research: more than looking into a mirror!

“Does disciplinary history matter?” This question was asked by Corbey and Roebroeks (2001a p 1) at the eponymous congress focusing on the history of
paleoanthropology and archeology. A negative answer assumes that studying the history of these scientific fields is an unsuitable job, at best a nice leisure time activity for retired colleagues. And since Landau (1991) implies in her book on *Narratives of Human Evolution* that modern paleoanthropologists are still only “storytellers,” a history of paleoanthropology is a double-sided problem: we have to ask whether there is really any need for a dubious historical approach to a biological discipline that only alleges to be doing science.

The allegation that paleoanthropology is not a serious and respectable field of research is not acceptable, although it may have its discreditable aspects (White 2000). In addition, what should one say about the history of science in general? Is disciplinary history no more than a waste of time for practitioners as well as historians of science? Experience shows that there is no uniform answer. However, if paleoanthropologists and historians of science can provide good suggestions for the improvement of the discipline, why should one give up studying the history of sciences or look on this discipline as a small-scale one?

The late Ernst Mayr—an outstanding modern Darwinist—gave a reasonable, albeit not exhaustive, classification of the various historical approaches: (1) elaborated lexicographic histories, (2) chronological histories, (3) biographical histories, (4) cultural and sociological histories, and (5) problematic histories (Mayr 1982). The essential point of all these approaches is that the historicist approach may give rise to reflection as Theunissen (2001) accentuates.

Although some may doubt whether the various approaches suggested (heuristics, source criticism, interpretation, hermeneutics, and analytics) will improve paleoanthropology, Corbey and Roebroeks (2001a) emphasize especially the heuristic value of historical studies. Dennell sees two further lessons from science history; one is awareness of the dangers of fragmentation, the other those of complacency. He considers the lack of dialogue and understanding between the anthropological disciplines as a fatal risk and warns: “There is still excessive specialisation and insufficient dialogue across the disciplines, especially where the terminology and techniques are unfamiliar” (Dennell 2001 p 66). Concerning the aspect of complacency, he explains: “It is always much easier to see the danger in retrospect, but perhaps one of the main lessons to absorb from the history of science is the danger of too many people becoming too comfortable for too long with an idea, just because so many agree with it, and have agreed with it so often in the past” (Dennell 2001 p 66).

These serious and severe arguments for the improvement of science by disciplinary history are valid for every field of study, i.e., “… area of intellectual endeavour that holds a common set of concerns, theories, and procedures or techniques that are intended to address a closely connected web of problems” (Shipman and Storm 2002 p 108).
A major aspect of biological anthropology is that the present is inevitably rooted in the past. For this reason, Dennell (2001 p 65) sees the study of human origins as “... a search for windows that should give us access to the past through fossil specimens, stratigraphic and climatic changes, inferences from the world around us, and the like.” Paleoanthropologists as well as prehistorians and archeologists seek windows to the past but use different sets of keys. A fatal danger is, however, that we may mistake a mirror for a window and simply extrapolate onto the past our own views and prejudices about the present. The important point here is, as L.P. Hartley puts it: “... the past is a foreign country, they do things differently there” (Foley 1987 p 78). For this reason, Foley continues that “The past cannot just be invented or imagined, nor reconstructed solely from observations of the way the world is at the present.” This brings the task and the challenge of paleoanthropological research and other evolutionary sciences to the fore: we are essentially creating models! (Foley 1987; Jones et al. 1992; Henke and Rothe 1994; McHenry 1996; Delson et al. 2000; Henke 2003a, b, 2004, 2005). This kind of approach (Figures 1.1 and 1.2) is by no means narrative but is rather contextual hypothesis testing; and even if in some cases it is scientific speculation, the accent is on the science (White 1988; Henke and Rothe 1994; Henke 2003a). Every scientist needs to arrive at innovative solutions within a channeled imagination.

The gift of Darwin’s theory is “... that there was no blueprint to be followed, only unfoldings of opportunity,” as Howells (1993 p 14) puts it. If the magnificent panoply of life today is the outcome of a real historical-genetic process without a plan, how do we explain the patterns and processes? Darwin’s theory is uncontested as the center of the whole science of biology. In Darwin’s Dangerous Idea, Dennett (1995, blurb) compares the theory of evolution to a universal acid, an imaginary “... liquid that is so corrosive that it will eat through anything!” and asks “Is nothing sacred?” Every traditional concept that tries to explain our existence has to compete with Darwin’s revolutionized worldview. As a consequence of Darwin’s theory of life, even human beings can no longer be explained in a teleological way as expressed by Dobzhansky (1900–1975) in his famous dictum: “Nothing in biology makes sense except in the light of evolution” (Dobzhansky 1973).

Common sense mainly considers paleoanthropology as the study of human fossils and a descriptive and broadly narrative discipline that is dominated by poorly researched and media-friendly “findings” that cause changing views on the process of human evolution. But is the history of paleoanthropological disciplines in fact something more than the demonstration of “... a road full of errors, freak opinions and bizarre concepts finally discarded” (Corbey and Roebroeks 2001a p 1)? Most anthropologists today agree that paleoanthropology is, like other categories of evolutionary biology, a serious subject involving
hypothesis testing and scientific modeling (Foley 1987; White 2000; Wood and Richmond 2000). They are aware that data ascertained from fossils do not speak for themselves and that for this reason the scientific approach involves the creation and testing of hypotheses and theories (Figure 1.3). It is by doubting theoretical insights that we come to questioning; and by questioning, we may perceive the truth—or what we think to be the truth (Popper 1959a, b, 1968, 1983; Foley 1987; Mahner and Bunge 2000; Vollmer 2003). Stronger theories are those that are optimally corroborated; however, even well-tested general theories may conceivably be refuted. Paleoanthropology and other biological subjects are not, like physics, empirical sciences sensu stricto, but this does not mean at all that it is a narrative subject; storytelling is frowned on in every science, and we agree with Kroeber (1953 p 358) who stressed that, “. . . there exists basically only one kind of fundamental science. All genuine science aims at the comprehension of reality, and it uses both theory and evidence, in combination, to achieve this comprehension.”
Like anthropological scientists, paleoanthropologists are only able to establish a reductionistic view of our *conditio humana*, but this is still an essential role as witness of the great scientific and public interest of this discipline. Heberer (1968a) used the terms “Jetzbild” and “Jeweilsbild” (meaning *status quo*) to intimate the changeability of our knowledge and the fact that every paleoanthropological report will be outdated very soon after it is published (Hoßfeld 1997, 2005a, b).
1.1.2 Darwin’s perspective on life processes

The paradigmatic change from a traditional static view into an evolutionary dynamic concept in the beginning of the second half of the penultimate century resulted in the recognition that humans are an integrated part of a historical process. The so-called “Darwinian Revolution,” triggered by Darwin’s masterpiece from 1859, remained in the following decades in a long-lasting state of confusion. As Bowler (1988) demonstrates in his historiography *The Non-Darwinian Revolution*, there were fundamental misunderstandings of Darwin’s ideas. In his judgement, the impact of evolutionism on late nineteenth-century thoughts has been tremendously overestimated by historiographers (Desmond and Moore 1991; Hemleben 1996).

Traditionally, it is assumed that the Darwinian Revolution in biology provided the impetus for a new evaluation of human origins, and Bowler claims that this assumption is valid up to a point. “Because of religious concerns, Darwin and his followers knew that they would have to explain how higher
human faculties had emerged in the course of mankind’s evolution from the apes” (Bowler 1988 p 141). The complex scientific answers within the given frame of ever-increasing biological facts and “disciplinary matrix” sensu Kuhn (Chamberlain and Hartwig 1999) essentially contribute to our self-image and orientation. An argument often given for the scientific necessity of paleoanthropological research is that humans have to know where they come from to decide where to go but “How [do] we know what we think we know” to borrow a phrase from Tattersall’s (1995) eponymous textbook.

Today’s paleoanthropology or human paleontology is a subdiscipline of evolutionary biology that aims to describe, analyze, and interpret the process of human evolution mainly through a vast set of inductive approaches and deductive hypothesis testing (Foley 1987; Henke and Rothe 1994; Wolpoff 1999; Tattersall and Schwartz 2000). If we want to know more about our origins, there are three basic approaches available to reconstruct our evolutionary history (Washburn 1953; Henke and Rothe 1994, 1999a; Wood 2000):

- First, the primatological approach; one can study the closest living relatives to understand the evolutionary context; such work includes field and laboratory work on behavior and cognition and the comparative morphological, physiological, serological, cytogenetical, molecular biological, and genetical studies (Martin 1990; Jones et al. 1992; de Waal 2000; Jobling et al. 2004).
- Second, the paleoanthropological approach; one can reconstruct our evolutionary history from the recovery and analysis of any relevant fossil evidence (Aiello and Dean 1990; Henke and Rothe 1994, 1999a, 2003; Henke 2003a).
- Third, the population genetic approach; one can study the phenetic and genetic intergroup and intragroup variation of recent human populations to provide clues between the geographical samples and their evolutionary history (Jones et al. 1992; Freeman and Herron 1998; Jobling et al. 2004).
- Finally, there is additional information on prehistoric human activities from cultural findings, i.e., the archeological record, and behavioral fossils, e.g., footprints (Klein 1989; Gamble 1999).

Current paleoanthropological research does not only ask what our forerunners looked like and when, where, and how they evolved but also specifically asks, for example, why humans evolved while other primate species died out (White 1988). We have to reconstruct the ecological niche of the fossil humans to define
the determinants that caused adaptation in human evolution, a process sometimes defined as hominization, although some anthropologists argue that this term is misleading (Delisle 2001). When using this perception, we should be aware that it describes a teleonomic process sensu Pittendrigh (1958). In paleoanthropology—as in other life sciences with a chronological perspective—the experiment is the historical process of nature itself. We have correspondingly to interpret this process within the general principles of evolutionary theory ex post factum, and we have to take into account all the problems that arise from the epistemological difficulty known as subject–object identity (Riedl 1975; Mahner and Bunge 2000; Vogel 2000; Vollmer 2003).

1.1.3 Why a scientific historical approach to paleoanthropology?

The present review of the historical development of paleoanthropology as a multifaceted biological subject is intended to focus on its cultural and social background and its many problematic time-specific aspects. This historical point of view promises some explanations concerning the following aspects:

- Which paradigmatic changes in evolutionary thinking guided the field of paleoanthropological research?
- Which cultural, social, and scientific reasons decelerated or accelerated the progress of paleoanthropology?
- Which outstanding scientists and what ideas brought about the integration of biological, geological, and archeological research?
- What was the country-specific impact on the constitution of paleoanthropological research?
- What underlies the successive development from Darwinism to neo-Darwinism, and of the Synthetic Theory and “Modern Synthesis,” respectively to the System Theory of Evolution as the concept and strategy of paleoanthropological research?
- Is paleoanthropology a fossil- and/or media-driven science, triggered by the discovery and public advertisement of exceptional hominin fossils?
- What is the impact of innovative biological techniques in times of multimedia on current paleoanthropology and its image?
- If the accusation is correct that many paleoanthropologists offer poorly researched but media-friendly “findings” (White 2000), how can historic studies on paleoanthropology contribute to a new orientation?
1.2 Paradigmatic change in the nineteenth century: step by step

1.2.1 Darwin’s forerunners, especially in France and England

The biblical view of the permanence of species expressed by Linnaeus’ sentence “Species tot sunt diversae, quot diversas formas ab initio creavit infinitum ens” was the underlying dogma of the Genesis and the Judaic and Christian tradition. Although animal fossils had been described long before Darwin’s theory was published, they were interpreted as witnesses of “lost worlds” within cataclysm models and not as evidence of a real historical-genetic process.

Georges Cuvier (1769–1832), the outstanding French comparative anatomist, did pioneering research on mammalian fossils and contributed to the self-consciously new science of geology. He began to understand that fossils truly represent remains of once-living organisms and argued for the reality of extinction caused by sudden physical events, so-called “catastrophes.” Cuvier first opened up a geohistorical perspective that is now appreciated as his most important legacy to science (Rudwick 1997). Besides this, he adamantly rejected “transformist” explanations. Although he was doubly on the wrong track and his remark “l’homme fossile n’existe pas” slowed the development of thinking on human evolution, Rudwick’s interpretation of the primary texts demystified Cuvier, who was one of the first to professionally plan his research. His approach had an important influence on the scientists of his time.

One of the outstanding opponents of catastrophism was Sir Charles Lyell (1797–1875), British geologist and popularizer of uniformitarianism. He formulated one of the most basic principles of modern geology, the belief that fundamentally the same geological processes that operated in the distant past also operate today. *Principles of Geology*, his specific work in the field of stratigraphy, was the most influential geological work in the middle of the nineteenth century and did much to put geology on a modern footing.

In spite of much progress in natural scientific thinking, the early explanatory approaches of evolutionary theorists were not able to replace traditional views. All pre-Darwinian explanations of diversity and variability were regarded as just another story of natural history because they failed to explain the driving force of evolution.

The evolutionary theory of Jean Baptiste de Lamarck (1744–1829) proved to be a nonvalid explanation for transformation. However, Charles Darwin (1809–1882) looked upon this retrospectively as an “… eminent service of arousing attention to the probability of all changes in the organic, as well as in the
inorganic world, being the result of law, and not of miraculous interposition” (Darwin 1861, preface).

While Lamarck’s theory triggered Darwin’s evolutionary thinking on “transmutation” of species, it was foremost Lyell’s Principles of Geology and Thomas Malthus’ essay on the Principle of Population (which stated that the population size is limited by the food resources available) that inspired Darwin to his multifaceted approach to deciphering the biological principles of evolution. He defined the fundamentals and described evolution as a self-organizing process by a mutation-selection mechanism without the necessity of a creator or deus ex machina. The driving force of this event, natural selection, codiscovered by Alfred Russell Wallace (1823–1913), is the central explanation of the evolutionary process.

Darwin’s and Wallace’s legacy, the theory of natural selection, ultimately led to a paradigmatic change, a totally new view of the development of life systems including human origins. The vintage philosophical questions “Who are we?,” “Where do we come from?,” and “Where are we going?” were transferred from the metaphysical and the philosophical to a biological focus. They created new and important existential questions. Kuhn (1962) saw the truly revolutionary aspect of Darwin’s theory not in its evolutionism but powerful rejection of the traditional, teleological view of nature. How explosive Darwin’s evolutionary theory was, and how conscious Darwin was of this, is reflected in the fact that he hesitated to deal with the questions of human evolution. The first edition of his classical opus On the Origin of Species by Means of Natural Selection, or the Preservation of favoured Races in the Struggle for Life (Darwin 1859) provides proof of this feeling of insecurity. It took him twelve years to publish his ideas in The Descent of Man and Selection in Relation to Sex (Darwin 1871). His innovative focus on human origins set the context for many of the themes of paleoanthropology during the following century. The anthropological challenge within the dynamic evolutionary concept was how to explain ourselves without compromising our posture. Altner (1981a p 3) verbalizes the existential problem as follows: “Der neuzeitliche Mensch ist aus allen ihn übergreifenden Sinnbeziehungen herausgefallen und auf sich selbst und sein Werden zurückgeworfen.”

Evolutionary thinking was widespread during the nineteenth century as various science historians have shown. Bowler (1988 p 5) suggests in this context: “... that Darwin’s theory should be seen not as the central theme in the nineteenth-century evolutionism but as a catalyst that helped to bring about the transition to an evolutionary viewpoint within an essentially non-Darwinian conceptual framework.”

Nowadays we know that most late nineteenth-century evolutionism was non-Darwinian as “... it succeeded in preserving and modernizing the old
teleological view of things”; however, it was a revolution “... in the sense that it required the rejection of certain key aspects of creationism,” as Bowler (1988 p 5) says (see also Desmond and Moore 1991). The heart of Darwin’s materialism, the theory of natural selection, had little impact until the twentieth century. For this reason, the Darwinian Revolution did not take place in the second half of the nineteenth century and remained incomplete until the synthesis with genetics in the twenties and thirties of the last century. But even after this breakthrough, there was no straight scientific approach in paleoanthropology, until anthropologists appreciated the essential corollary of Darwin’s theory that we are only “another unique species” (Foley 1987).

In retrospect, it becomes obvious that the earliest “evidences” of human evolution were disregarded and misinterpreted. Fossils do not speak, but they give silent witness which is a dictum in paleontology. One can only get morphological, ecological, or taxonomical information within a concise methodological approach. Apparently easy paleoanthropological questions about the space and place of human origins do not necessarily have easily obtainable answers, and for this reason it requires rigorous efforts to establish a sophisticated research design and adequate methodology to find solutions for the key questions given earlier (See the section “Why a scientific historical approach to paleoanthropology?”).

As an evolutionary substratum was missing at the time when William Buckland (1784–1856), professor at the University of Oxford, discovered the first human fossil, the “Red Lady of Paviland” at Goat’s Hole in South Wales in 1823, he totally misinterpreted this 26-ka old find (Sommer 2004). Buckland considered the skeleton as of postdiluvian age and was unwilling to attribute any great antiquity to the Upper Paleolithic fossil skeleton.

“For most of the nineteenth century, no one believed or anticipated discoveries that would demonstrate a history of humans and their ancestors stretching back over more than a few thousand years,” write Trinkaus and Shipman (1993 p 9). Although savants struggled with evolutionary ideas for decades, the belief persisted that the human past differed from the present only in the “primitiveness” of the ancient peoples, not in their very essence and being. Starting in the twenties of the nineteenth century, there sprang up one local natural history society after another. The Red Lady inspired the hunt for human fossils and artifacts. Kent’s Cavern in Torquay Devon, today recognized as one of the most important archeological sites in the British Isles, was excavated by John MacEnery and William Pengelly (Sacket 2000). They discovered an Upper Paleolithic skeleton in association with flaked stone tools. John Lubbock, the foremost British archeologist at that time, refused the report on “modern savages” written by Godwin-Austin and considered the findings as “improbable” (Trinkaus and Shipman 1993).
Phillipe-Charles Schmerling, a Belgian physician and anatomist, unearthed an infantile skull in 1829/1830 in Engis near Liège, which was diagnosed later as a Neanderthal fossil. The Engis child was the first specimen of its kind to be discovered (Schmerling 1833). During the same period, Casimir Picard, a physician and avid archeologist, was excavating prehistoric stone tools in France. His passion was experimental approaches to archeology as he attempted to make and use stone artifacts like those that were being found in excavations. Due to inadequate chronology of the artifact-bearing horizons, he was not able to calibrate some of his stone tools as Neolithic. But his experiments led him to conclusions about how the tools were manufactured. Picard developed for the first time systematic excavation techniques and a stratigraphic approach. While his innovative research was without wider impact on archeological progress, he impressed his friend Boucher de Perthes. This most influential aristocrat, who combined his romantic views on human origins with archeological fieldwork, argued for the existence of Pleistocene—or as he said pre-Celtic—humans, but his findings were at first disregarded by the scientific community. When in 1864 some of his findings were published in *The Anthropological Review*, the comment of the scientific board was downright British: “We abstain at the present from offering any comment on the above” (Trinkaus and Shipman 1993 p 44). Although Boucher de Perthes could not avoid the image of flamboyant enthusiast and “madman,” there finally came a change in the assessment of the hand axes as genuine tools. Finally, the precise excavation of the gravel beds of the Somme at St Acheul by the French amateur naturalist Marcel-Jérôme Rigollot (1786–1854) impressed a group of outstanding British colleagues, among others Charles Lyell, and led to the acceptance of the claim that the hand axes were associated with extinct mammal bones—but where did this leave the human fossils? (Klein and Edgar 2002).

1.2.2 Neanderthal case: “Neanderthals without honor”

The Neanderthal man from the Kleine Feldhofer Grotte in the Neander Valley near Düsseldorf was found by limestone workers in 1856 and described by the local teacher Johann Karl Fuhlrott (1803–1877). The fossil was the first early human specimen to be recognized as such. Discoveries like that from Engis (1829) and another from Gibraltar (found in 1848) were made sooner, but their nature became evident much later. Fuhlrott’s merit was that he realized the significance of the fossils, which the limestone workers took for animal bones. Luckily, the owner of the excavation site saved them at the last moment (Schmitz and Thissen 2000). Fuhlrott fought, together with the anatomist
Herrmann Schaaffhausen (1816–1893) who taught at the University of Bonn, for their acceptance as ancient remains from the diluvial age. Both were convinced that the morphological structure of the bones indicated a high-diluvial age. As the discovery of the fossil bones antedated the publication of Darwin’s *Origin of Species*, this specimen has often been apostrophized as first proof for human evolution. A deeper analysis of their contribution demonstrates that both protagonists of paleoanthropological research in Germany were far away from a concise interpretation in an evolutionary sense, although they looked upon their fossils as diluvial forerunner of recent *Homo sapiens* (Zängl-Kumpf 1990).

A contemporary of Fuhlrott and Schaaffhausen was Thomas Henry Huxley (1825–1895), the famous British zoologist, often referred to as “Darwin’s Bulldog” (Desmond 1997). However, Huxley was no Darwinian. Historians know the difficulty of accurate definition, and Hull (1985, 1988) gets to the heart of this problem when suggesting “… that Darwinians are simply those scientists who expressed loyalty to Darwin as the founder of evolutionism, whatever their beliefs about how evolution actually works” (Bowler 1988, p 73). Although Huxley was highly committed by Darwin’s theory, it is well known that he had essential problems with the selection theory. Further, he was strongly tempted by non-Darwinian ideas, e.g., internal factors that would produce changes independent of the environment. Not being really interested in adaptation, Huxley speculated that evolution might sometimes work in a saltatory manner (Bowler 1988; Desmond 1997). His position was that the continuity between humans and other animals does not detract from the inherent specialness of humans. The contemporary so-called proponents of Darwinism were not at all Darwinian evolutionists. In his famous papers on *Evidences as to Man’s Place in Nature*, Huxley (1863) gave morphological arguments for our relationship with recent primates and pointed to the scarce fossil record known in his time. In spite of contrary statements by many historians, Huxley said virtually nothing about human origins but concentrated exclusively on demonstrating the physical resemblances of humans and apes. Concerning the Neanderthal man from Germany, Huxley conducted a sophisticated comparison with anatomically modern skulls from Australian Aborigines and other aboriginal relicts, pioneering new ways of orienting and measuring skulls for easier comparison (Desmond 1997). His conclusion was that the Neanderthal skull emerged as an exaggerated modification of the lowest of the Australian skulls. Huxley stated that the brain of the Neanderthal man was of normal size for an ancient savage, and the stout limbs suggested to him a cold adaptation to glacial Europe. However, in no sense was this specimen “intermediate between Man and Apes.” He viewed the Neanderthals as a very “primitive race” of humans, “the most pithecoid of human crania yet discovered” (Huxley 1863 p 205). The Huxley-biographer Desmond (1997) illustrates this by
reference to Huxley’s diary entries: “Where, then must we look for primeval Man? Was the oldest Homo sapiens pliocene or miocene, or yet more ‘ancient’? How much further back must we go to find the ‘fossilized bones of an ape more anthropoid, or a man more pithekoid’?” Desmond concludes that Huxley was preparing the world for ancient semihumans.

The Irish zoologist William King proposed in 1864 the name Homo neanderthalensis, although his arguments for a separate species in the genus Homo were inadequate, not to say absurd. Since then, opinion has fluctuated as to whether the fossils should be considered as a separate species, H. neanderthalensis or H. sapiens neanderthalensis (a subspecies of H. sapiens). The “fate of the Neanderthals” is the trickiest controversy in paleoanthropology (Henke and Rothe 1999b; Henke 2003a, b, 2005; Finlayson 2004). The question of whether some or all of these fossils deserve a place in our direct ancestry or whether they can be viewed as a single lineage leading to and culminating in the classic Neanderthals of the last ice age is the long-lasting taxonomic problem in paleoanthropology. What became very soon apparent with Huxley’s Evidences was the tremendous need for an extension of the fossil report—since that time colloquially termed as “missing links”—and for an improved comparative methodology to analyze and interpret the fossils of recent primates.

1.3 Theoretical and methodological progress in paleoanthropology since Darwin

1.3.1 Successive discovery of the paleoanthropological background

In Darwin’s time, it was already evident that the scarce evidence of hominin life in the past does not allow the neglect of any clues. We need all available sources to reconstruct our evolutionary history, and these interpretations rely overwhelmingly on fossils. These latter are obviously mute; for this reason, one has to formulate hypotheses about the biological and phylogenetical role of the extinct taxa, and the only reliable approach to increasing our knowledge of the lost worlds is to compare them with recent sets of well-known phenomena.

This scientific process started very soon after the fulguration (sensu Popper) of the pre-Darwinian interpretation of fossil specimens as documents of species of former times and Darwin’s evolutionary theory. The systematic search for phylogenetic forerunners of recent taxa began. The most dramatic part of the Darwinian paradigm focused on the question of how humans evolved from archaic primates. What did the hypothetical species transitional between apes
and man look like? When, where, and how did the missing link live, a term created in 1861 by Asa Gray (Shipman and Storm 2002). Darwin’s evolutionary theory of natural selection did not automatically provide an answer to that question, and Darwin himself was cautious enough not to give a premature answer. But he had provided a new framework in which all these questions could be answered. While the public longed for strong proof of human evolution, Darwin gathered all available arguments for more than 10 years. Finally he published his brilliant anthropological volumes *The Descent of Man and Selection in Relation to Sex* (1871) and *The Expression of Emotions in Animals and Man* (1872). Both books deal with human evolution and particularly with sexual selection, whose enormous evolutionary impact was first understood only around 100 years later, when the sociobiological paradigm emerged (Wilson 1975; Vogel 1982; Miller 1998; Voland 2002; Voland and Grammer 2002).

During the 1860s, Darwin’s ideas were widely popularized. However, there emerged much scientific skepticism at that time as the laws of heredity worked out by Gregor Mendel (1822–1884) in 1865 remained unknown until the twentieth century. Beside Darwin’s British supporters, especially Thomas H. Huxley and Charles Lyell, it were the German geologist and paleontologist Friedrich Rolle (1827–1887) and the zoologist Carl Vogt (1817–1895) who advocated Darwin’s theory (Rolle 1863; Vogt 1863).

Even more committed and sarcastic than the “Affenvogt” was Ernst Haeckel (1834–1919), an outstanding German biologist who sagaciously fought against the “ape complex.” He is best known for his *recapitulation law* (ontogeny recapitulates phylogeny), a highly controversial assumption. After reading *The Origin*, he became a powerful and eloquent supporter of evolution. Although Haeckel admired Darwin’s theory, concerning his own evolutionary thoughts he remained an orthogradualist, and concerning the concept of the “survival of the fittest,” a Lamarckian. Haeckel was not really supportive of natural selection as the basic principle of evolution, and his interest in fossils and paleoanthropology was small. He was convinced that due to the intertwining of phylogeny and ontogeny, ontogenetic structures were sufficient evidence for evolution (Haeckel 1898, 1902, 1905, 1922; Heberer 1965, 1968b, 1981; Hoßfeld and Breidbach 2005; Kleeberg see www).

Despite misunderstanding many of Darwin’s thoughts, Haeckel inspired the public and colleagues with his enthusiasm for evolution and animated the debate. As he was highly motivated by his anti-Christian attitude, his influence in science faded, especially when he created his monistic theories and dabbled in esoteric fields (Hoßfeld 2005b; Kleeberg see www). He gave paleoanthropology an essential impulse by publishing the first phylogenetic tree (Figure 1.4) that
included humankind. Darwin commented on this: “Ihre Kühnheit läßt mich jedoch zuweilen erbeben, aber, wie Huxley bemerkte, irgend jemand muß eben kühn genug sein und einen Anfang machen, indem er Stammbäume entwirft” (Darwin’s letter to Haeckel, November 12, 1868) (Schmitz 1982). As the scarce fossil record only allowed a very hypothetical pedigree, there was much courage needed indeed. Haeckel postulated a forerunner species *Pithecanthropus*
alalus—a speechless ape-man—a missing link, which he believed lived during the Pliocene in Southeast Asia or Africa. Within an orthogenetic pedigree, he posited a primitive species—which he named Homo stupidus—between this “ape-man” and the recent H. sapiens. Around 30 years later, fossils were found in the postulated Asian region by the Dutch physician Eugene Dubois (1858–1940), which roughly fitted the expectation of a Pithecanthropus (Bergner 1965).

Meanwhile a focus of research was the phenomenon of the Ice Ages and the discovery of Upper Paleolithic man and Ice Age cultures (Trinkaus and Shipman 1993; Sackett 2000). Although human fossils were rare at the time of Darwin’s revolutionary discovery, there was much evidence from animal bones, molluscs, sediments, and other materials to give insight into ancient populations. Further, there were ever-increasing indications of long-term fluctuations in the earth’s climate. Geologists, like Agassiz, Geike, and Lyell as well as Brückner and Penck, established a Pleistocene framework of successive glaciations, and archeologists strove to establish the antiquity of human ancestry through the association of stone tools with extinct animals. The geological research resulted in the Alpine model, a chronological system of glaciations that gave a framework for the ongoing discovery of Neanderthal fossils.

As biological, anthropological, geological, and archeological data came together within the frame of the evolutionary theory during the second half of the nineteenth century, many scientific societies were founded, which supported all kinds of scientific research.

Rudolf L.C. Virchow (1821–1902), a famous German physician and anthropologist sensu lato, best known for his guiding research in cellular pathology and comparative pathology, was a universal scientist and liberal politician who founded the German Society of Anthropology, Ethnology, and Prehistory in 1869 (Degen 1968; Andree 1976; Schipperges 1994; Goschler 2002; Trümp 2004). He included humankind in the historicization of nature and came to the conclusion that H. sapiens was “Post-Historie” (Goschler 2002 p 322). For that reason, he was highly skeptical about the validity of Darwinian theory concerning our own species and doubted the phylogenetic classification of the species H. neanderthalensis, as the Irish zoologist William King had dubbed the skeleton from the Kleine Feldhofer Grotte (Stringer and Gamble 1993; Trinkaus and Shipman 1993; Schmitz and Thissen 2000). Due to his “pathologist view,” he interpreted the Neanderthal-derived features or apomorphies as pathological features resulting from arthritis; further from the erroneous information that the skeletal remains were associated with polished stone tools (an indicator for the Neolithic), he concluded that the Neanderthal man must have lived in recent times (Schott 1979). Thus, not all human fossils known at that time were accepted as convincing evidence of our ancestry, especially given their widely uncertain dating.
Neither Virchow nor Haeckel pushed paleoanthropological research, the former from misinterpretation of the facts and skepticism on Darwin, the latter from his conviction that ontogenetic research delivers sufficient information to demonstrate phylogenetic evolution. Virchow’s interest was much more in prehistoric anthropology and ethnology, from the point of view of the decoupling of natural and cultural evolution. The retrograde view that a missing link does not exist was admired by the Christian church, and when *Pithecanthropus erectus*, the so-called “Java Man,” was described, he thought that the bones represented a giant gibbon.

Virchow’s skeptical attitude concerning *Pithecanthropus* as well as his critical interpretation of the Neanderthal fossil as a pathological individual lessened the biological impact of a premature “palaeoanthropology” during the second half of the nineteenth century (Trümper 2004). This holds true for the English and French scientific scenes as well. Although the physician Paul Pierre Broca (1824–1880), the founder of the Société d’Anthropologie de Paris in 1859, was a pioneer of comparative anatomy and anthropology, he never accepted the Neanderthals as fossil documents. His interest was in understanding the patterns of variation in order to understand the significance of anatomical differences. For this reason, he became one of the first to use statistical concepts in establishing anthropology as a scientific discipline in contrast to medical science. In 1882, his French colleagues Quatrefages and Hamy published *Crania ethnica*, a monograph which exemplifies the huge interest in recent cranial variation that dominated the anthropological discipline.

Eduard Lartet (1801–1871) was the first to describe the primate genera *Dryopithecus* and *Pliopithecus*, but much more important was his discovery of signs of prehistoric art made by early humans. The fossil ivory carving of La Madeleine, found in 1864, was presented at the world exhibition in Paris 1867 and raised tremendous interest.

In the following period, neither the discoveries of human fossils from La Naulette in Belgium nor those of Pontnewyydd (Wales), Riveaux (Southern France), Šipka, Mladeč, and Brno (Czech Republic) were able to convince the European scientific community of the human antiquity. Even the analysis of the Spy fossils, which had been discovered in Belgium in 1886, did not slow the rejection of evolutionary thoughts. Trinkaus and Shipman (1993 p 132) summarized: “The man of the Neander Valley remained without honour, even in his own country.”

In the motherlands of evolutionary thinking, France and England, Paleolithic archeology dominated the paleoanthropological discussion and began taking shape as an organized scientific field of research in the 1860s. Sackett (2000 p 38) puts it this way: “… discovering the Paleolithic became a matter of empirically demonstrating that human remains and artefacts could be found in association with the remains of extinct animals belonging to the deep time of earth history.”
Progress was for the first time possible through the scientific recognition of the Pleistocene geological epoch, i.e., the interpretation of fossils within a solid geological background. Although Cuvier and Lyell had done indispensable scientific work to understand the past, the first assumed that the changes came about by a series of revolutions, while the second, although he had major objections to Cuvier’s theory of catastrophism, was no evolutionist either. The challenging question for the evolutionists was how to provide empirical data concerning the existence of “diluvial” and “antediluvian” early human populations. As these workers had to rely on the research of the paleontologists and the archeologists, paleoanthropological science was becoming multidisciplinary even at this early stage. The evidence from the Paleolithic record was mainly from data from stream gravel terraces, rock shelters, and bone caves. As Sackett (2000 p 42) mentions, from the 1820s until 1859 there was a series of discoveries in France (especially in the Perigord), England (Paviland bone cave near Swansea, Wales; Kent’s Cavern, near Torquay, Devonshire), and Belgium (Engis near Liège). The research resulted in the assignment of Pleistocene fauna to deep geological times, but it did not support evolutionary thinking due to the many alternative explanations available. The consequent question was whether actual human remains existed in association with Pleistocene animal fossils and undoubted artifacts. The immediate question of human antiquity came up with the discussion of the fossils from the Neanderthal in Germany and Darwin’s evolutionary theory. Most of the geologists and paleontologists remained skeptical; they saw no proof of a high antiquity of humankind from evidence from the bone caves or gravel terraces. One reason for their skepticism resulted from the archeological work of Jacques Boucher de Perthes, director of customs at Abbeville, France, whose empirical evidence was much doubted. As consequence of his having “... found much too much,” as Sackett (2000 p 45) puts it, the Bible continued to dominate everyday metaphor; and ironically enough, the successful archeological research in the Near East, Egypt, and Palestine solidified the traditional view that human-kind was unique and doubtless recent. In spite of many convincing facts—as retrospectively gauged—from archeology, the social establishment of the mid-nineteenth century maintained the older view.

An opportunity for change came in 1858, when Brixham Cave near Torquay on the Devon Coast was discovered, and outstanding scientists like Hugh Falconer (1808–1865), Charles Lyell, Richard Owen (1804–1892) supervised excavations there. William Pengelly (1812–1894), a local schoolteacher and geologist, was able to gather, by a new method of layer-by-layer excavation, thousands of animal bones including those of hyena, cave bear, rhinoceros, and reindeer. The impact of these fossils on the question of human antiquity would have been zero if Pengelly had not found undeniable artifacts, which he
described as “knives”. These chipped stones from Brixham Cave challenged the received opinion about human antiquity in 1859. While the belief in human antiquity of the excavator and some colleagues was confirmed by the association of fossil bones and the hand-axes, others like Owen did not agree and thought that the animals had not become extinct until geologically modern times.

New aspects came into the stagnating discussion when the implements of the Brixham Cave were compared to the finds at Abbeville and Amiens, which had been excavated by Boucher de Perthes. The ultimate convincing facts came when the English team, digging in the Somme terraces, was able to document a hand-axe in place in a fossil-bearing stratum at St Acheul. This was the turning point as Pengelly, Prestwich, and Lyell were then able to convince the British establishment of the antiquity of humankind. The French scientific community, which had contradicted Boucher de Perthes’ interpretations for many years, now no longer rejected the idea of human antiquity. However, some French scientists, like the zoologist Isodore Geoffrey St Hilaire (1805–1861) or Eduard Lartet (1801–1871), had been more or less convinced about human antiquity before, but the discovery of human teeth intermixed with fossils of cave bear and hyena in a cave near Massat in southern France brought about final acceptance. Lartet published the ultimate proof in 1860. He described cut-marks on fossil bones that had been made by stone tools when the bones were still fresh. This was the essential evidence of contemporaneity of humans and extinct animals, and it signaled the start of intensified geological research. The glaciological research aimed at structuring the Pleistocene epoch helped to put the human antiquity into a chronological frame; and the amalgamation of archeological and geological facts brought up a new era that started with Lyell’s first edition of his famous *Geological Evidences for the Antiquity of Man* (1863). The coming together of diverse aspects of the cultural and natural sciences ultimately yielded an innovative conception of man and his origin (Daniel 1959, 1975; Trinkaus and Shipman 1993; Sackett 2000; Murray 2001).

### 1.3.2 Southeast Asia as supposed cradle of humankind

If paleoanthropologists had to answer the question of which fossils had the most exceptional influence on human evolutionary thinking, they would, of course, include the *Homo erectus* fossils from Java alongside those from the Neander Valley. The assessment is very easy to understand: first, there is a hero, a young, enthusiastic physician from the Netherlands, Eugene Dubois, who feels inspired by Darwin’s theory and Haeckel’s preliminary draft of a link between the lesser apes and earliest human populations; he joins the army as military surgeon and embarks for Indonesia. Beside his service in the army, he is looking for the so-called
missing link, *P. alalus*, as Haeckel had dubbed the speechless and small-brained human species (Shipman 2001; Shipman and Storm 2002). Second, this paleontological amateur is successful in discovering a fossil human tooth and then a skullcap in the gravels of the Solo River. He proposes at first the name *Anthropopithecus* and then changes it to *Pithecanthropus*, the name given by Haeckel. Finally, a stroke of good fortune leads to the discovery of a human femur, which seems to belong to the *Pithecanthropus* fossils, which causes the species to be named *erectus*. Third, Dubois, the man who found the posited missing link, gets into more and more trouble with his critics and, due to severe personal problems, the end of his career is tragic. Since Dubois was neither an accidental discoverer nor a paranoid eccentric person, as science historians and colleagues (v. Koenigswald 1971) have sometimes characterized him, so the reinvestigation of his lifework gives a less discrediting view (Shipman 2001; Shipman and Storm 2002).

If one takes all aspects of this story together, it shows the main characteristics of a myth. On the one hand his unbelievable luck and on the other hand, his unyielding, difficult character and his stubborn nature made Dubois an interesting public figure. While some historians like Erickson (1976) look upon Dubois as an unimportant figure in paleoanthropology, others like Haddon (1910), Theunissen (1981), or Shipman (2001) see him as one of the founding fathers of paleoanthropology (Shipman and Storm 2002).

Did Dubois’ essential discovery coincide with a paradigm shift in paleoanthropology? While Howell (1996 p 4) stated that the entire field of paleoanthropology is “... close to a paradigm state without yet having achieved it,” Chamberlain and Hartwig (1999 p 42) suggest, “... that the validity and promotion of knowledge claims in palaeoanthropology are explicitly Kuhnian and that future epistemological progress depends on acceptance of both Kuhnian and positivist approaches to knowledge-building.”

In opposition to Chamberlain and Hartwig’s opinion, Cartmill (1999 p 46) stated that: “Whatever a paradigm is, normal science consists of attempts to ‘articulate’ a paradigm by answering questions, verifying predictions, and solving sticky problems in paradigmatic terms.” He continues: “Conceptual change in science is perpetually going on at all levels, and is not ordinarily concentrated in punctuational events that can be distinguished as ‘revolutions’.”

Whatever position one adopts, there are obviously good reasons to regard Dubois as a founder of paleoanthropology. According to Shipman and Storm (2002 p 109), founders must have special qualifications, e.g.,

- A pivotal discovery of fossils or artifacts
- Development of an innovative technique for the description and analysis of discoveries
A new framing of the problems or questions of the fledgling field
A broad dissemination of information or debate about the subject, which serves to make it a matter of wide concern
The provocation of a general reaction or response from potential colleagues.

The last point fits with the Machiavellian fact that an invention needs the attention of the scientific community to become common currency. One may ask what would have happened to Dubois’s discovery in modern times. The rules of “The Economy of Attention,” formulated by Georg Franck (1998a, b), list the following stepwise pattern: “Attention by other people is the most irresistible of drugs. To receive it outshines receiving any other kind of income. This is why glory surpasses power and why wealth is overshadowed by prominence.”

While Haeckel, Broca, and other scientists focused on the comparative anatomy and embryology as proof of human evolution, Dubois was the first who implemented a new strategy. Since he realized that human evolution is a chronological process, which must have happened in preferred localities with specific ecological niches, he set out for Southeast Asia, promised by Haeckel’s fictive pedigrees as a possible “cradle of mankind” where the mysterious missing link should have lived.

Dubois was the first to write a detailed monograph on a hominin fossil, and he applied for the first time metrical and mathematical procedures for the calculation of brain volumes and stature heights to a human fossil. A critical evaluation of his work by Shipman (2001) shows that his scientific work was innovative and erudite, contrary to reports circulated by paleoanthropologists and science historians. The contemporary reviews of his 1895 monograph by, e.g., the German anatomist Wilhelm Krause and the multitalented scientist Rudolf Virchow were scathing, just as were those of the British, French, and Swiss scientists. On the other hand, it was no surprise that Haeckel’s comment was positive. The skepticism of part of the scientific community incited him to tremendous activity, and there resulted a flow of papers on *Pithecanthropus*. It is thanks to Dubois that the focus on human fossils increased (Shipman and Storm 2002). The market place for human fossils and paleoanthropological discussions was open (Sander 1976).

Among the scientific activities of the anthropological organizations in different European countries, e.g., the Gesellschaft für Anthropologie, Ethnologie und Urgeschichte in Berlin or the Société d’Anthropologie de Paris as well as the Royal Anthropological Society of Great Britain, at the turn of the penultimate century, interest in the diversity of recent humankind was paramount. While many activities were concentrated on the typological classification of recent populations as well as prehistorical and archeological research, paleoanthropological
problems and fossils played only a minor role. Dennell (2001 p 52) designates the period from ca. 1870 to 1930 as the “Age of Prejudice so far as European (and North American) perceptions of non-whites is concerned.” The dominating theme was the racial prejudice of fixity and inequality of races. While this attitude did not change when the first non-European fossil caught the interest of the scientists and the public in general, it introduced a new aspect of human evolution: the confrontation of eurocentristic typological views with paleoanthropological facts.

In the light of the *Pithecanthropus* fossils, the Neanderthal problem reached a new dimension. Virchow’s diagnosis implied that the Neanderthal man was diseased with rickets as a child and arthritis as an adult. To many, this explanation of the special bony features of Neanderthals sounded far-fetched (Trinkaus and Shipman 1993). There was a fundamental need for appropriate comparative biological research and a reasonable taxonomic approach. With the benefit of the hindsight, one can see that in those times there was no theoretical basis for elaborated paleoanthropological research, since the anatomists as well as the archeologists were concentrating on case studies, while zoologists, like Haeckel, were focusing on other topics than merely paleoanthropology. The end of the nineteenth and the beginning of twentieth century yielded exciting discoveries of human fossils (*Table 1.1*). The obvious lack of a sophisticated theoretical basis

and elaborate methodological skills in paleoanthropological research gradually led to the development of a new field of evolutionary biology.

The best basis for such a development existed in France, where Pierre Marcelin Boule (1861–1942), who was a qualified geologist, paleontologist, and archeologist, unified all necessary attributes to establish a paleoanthropology. His classical description of the Neandertal skeletons from La Chapelle-aux-Saints (Boule 1911–1913) was a landmark in the history of human paleontology (Heberer 1955a). Contemporaneously, the German anatomist Gustav Schwalbe (1844–1916) analyzed a skull fragment from Eegisheim as well as the famous Javanese *Pithecanthropus erectus* (Schwalbe 1906; Fischer 1917): research that is regarded as critical to the founding of paleoanthropology as a research field of its own. Heberer (1955b p 298) comments on this: “An die Stelle ungenügend fundierten Theoretisierens tritt jetzt in der menschlichen Fossilforschung die exakte Empirie.” Albeit this sounds somewhat effusive, the empirical approach to the morphological and metrical analysis of the fossils allowed an independent development, separated from geology and archeology. This view characterizes, on the one hand, the lacking cooperation of paleoanthropology as a biological field of research with the geosciences as well as the archeology/prehistory and, on the other hand, the overestimation of the scientific importance of quantifying morphological methods (Chaoui 2004; Hoßfeld 2005b). Both of these aspects hampered any essential progress in paleoanthropology for decades, the subject remained mainly narrative and descriptive (see Henke, 2006).

### 1.3.3 Development of principles and methodical skills in paleoanthropology

Neither Haeckel nor Virchow regarded paleoanthropology as a particularly important subject, and even anthropology itself was not a discipline of great significance in their times. The reason for the late establishment of anthropology as a separate biological discipline is, as Grimm (1961 p 1) suggested, that “... der Anthropologe viel weniger als der Zoologe oder der Prähistoriker oder der Anatom in der Lage schien, die Grenzen seines Faches zu bestimmen.”

In the first half of the twentieth century, paleoanthropology remained uncentered as physicians, anatomists, biologists, archeologists, and ethnographers from different viewpoints and with different intentions and aims all practiced anthropology. This becomes especially obvious if one looks from the more zoological fields of research across to archeology. The division of so-called explanatory natural sciences (erklärende Naturwissenschaften) from the comprehending humanities (verstehende Geisteswissenschaften) *sensu* Dilthey 1883...
(Groethuysen 1990) was completed at the beginning of the twentieth century, contingent on the obvious consciousness of superiority of natural sciences (Figure 1.5).

“verstehende Wissenschaft”
“comprehending science”

The rediscovery of Gregor Mendel’s laws in 1900 by Carl Correns, Erich von Tschermak-Seysenegg, and Hugo de Vries gave a push to evolutionary thinking. Around 1930, protagonists of neo-Darwinism like Ronald A. Fisher, John B.S. Haldane, and Sewall Wright developed around 1930 the basic principles of population genetics in the USA and induced a fruitful diversification of natural sciences. In the following period, the Russian geneticist and evolutionary biologist Theodosius Dobzhansky (1900–1975), the American paleontologist George Gaylord Simpson (1902–1984), the German evolutionary taxonomist Ernst Mayr (1904–2005), and finally the British biologist Julian Huxley (1887–1975) founded the synthetic theory of evolution, integrating additionally quite a number of neighboring disciplines to reconstruct the phylogenetic process of our own origin (Jahn et al. 1982; Jahn 2000; Junker 2004; Wuketits and Ayala 2005; Hoßfeld 2005b). The major principles of the Synthesis itself were subsequently enunciated
between 1937 and 1944 in three seminal books. While Dobzhansky (1937) focused on the gene, Mayr’s (1942) vantage point was the species and Simpson’s (1944) perspective was on the higher taxa. Tattersall’s (2000a p 2) assertion that “. . . the Synthesis was doomed to harden, much like a religion, into dogma whose heavy hand continues to oppress the science of human origins a half-century later” is controversial as is reflected in Foley’s statement (Foley 2001). However, before we discuss the consequences of the Synthesis, we shall have a closer look at paleoanthropology.

### 1.3.4 Fossils: hypotheses, controversies, and approaches

In the early beginning of paleoanthropology the main question was quite simple: is there a fossil record which proves the existence of our ancestors from ancient times? The protagonists of paleoanthropology soon recognized the need for a sophisticated empirical approach. The best basis for such a development existed in France, where Pierre Marcelin Boule (1861–1942), a qualified geologist, paleontologist, and archeologist, unified in persona all necessary attributes to establish a paleoanthropology. His classical processing of the Neandertal skeletons from La Chapelle-aux-Saints (Boule 1911–1913) became a landmark in the history of human paleontology (Heberer 1955a). He aimed to understand the patterns of variation and the significance of anatomical differences. For this reason, Boule invented special instruments for quantification(s) and simple statistical concepts to analyze the variation in human skeletons (Boule 1921, 1923; Boule and Vallois 1946, 1952). Boule established a paleontology of humans, later on called paleoanthropology, as a scientific discipline, but as evolution in itself was still regarded as a widely speculative myth, the debate on human evolution “… rose and fell like a tide in France, Germany, England, and the United States,” as Trinkaus and Shipman (1993 p 154) described the situation.

During the late nineteenth and the early twentieth century, the overestimation of quantifying procedures strongly affected the anthropological research, starting with the first representatives of anthropological chairs, Jena Louis Armand de Quatrefages de Breau (1855, Paris) and Marcelin Boule (1867, Paris), and Johannes Ranke (1886, Munich) and Felix v. Luschan (1900, Berlin). While Ranke was deeply opposed to the idea of human evolution, with Otto Schwalbe, just mentioned, Theodor Mollison (München), Felix v. Luschan (Berlin), Rudolf Martin (München), and Otto Schlaginhaufen (Zürich) successively advocated measuring techniques of every conceivable kind (Keller 1995; Chaoui 2004; Junker 2004; Hoßfeld 2005b). While Schwalbe was convinced that information on evolutionary history could only be gained from neo- and paleozoology, others
focused predominantly on typological classification of prehistorical populations and neglected broader paleoanthropological questions. This can only be understood by the fact that the conventional wisdom of that time was that modern “races” arose from types that were already separate in the early Pleistocene. For this reason, there was a big problem when Gorjanović-Kramberger (1906) described the fossils from Krapina, excavated in 1899–1905, in a voluminous monograph as belonging to a “man-eating” population (Radovčić et al. 1988). As this thesis was accepted by one of the most outstanding anthropologists at those times, Aleč Hřdlicka (Prague, later on Washington) who pushed paleoanthropological research using his influential position at the Smithsonian Institution, Krapina became a big challenge to the scientific community (Henke 2006).

Further controversies were born when descriptions of the Upper Paleolithic skeletons from, e.g., Chancelade, Grimaldi, Combe Capelle, Oberkassel, and the Neanderthals, as well as, e.g., Le Moustier, La Chapelle-aux-Saints, La Ferrassie, La Quina were excavated and published. There was special interest in the mandible from Mauer that was described in 1908 by Otto Schoetensack (1850–1912) as Homo heidelbergensis (Adam 1997; Wagner and Beinhauer 1997).

In England, the motherland of Darwinism, there was for a longtime little progress in paleoanthropology as the Darwinists were obviously “no Darwinians in the modern sense” (Bowler 2001 p 14). During the period from 1860 to 1940, a Darwinian style of explanation began to replace non-Darwinian developmental models stepwise, but a real breakthrough or turnover did not occur before World War II, largely due to the overwhelming influence of the paleontologist and geologist Arthur Smith Woodward and the zoologist Sir Arthur Keith as the leading authorities on human remains. Keith published An Introduction to the Study of Anthropoid Apes in 1896, followed by a monograph, The Antiquity of Man, which appeared in 1915. This publication on all-important fossil human remains founded his worldwide reputation and appeared in an enlarged edition in 1925. As can be seen from his textbook Concerning Man’s Origin (Keith 1927), he was at that time less convinced than he had been 10 years before that modern humans and extinct “primitive” types had lived contemporarily. In his volume New Discoveries, Keith (1931) rejected this interpretation given the strength of the arguments for an evolutionary branching of hominins. From the viewpoint of history of science, we have to ask why the leading “anthropologist” as well as his compatriot Sir Grafton Elliot-Smith (1871–1937) retained this view for such a long period, in the face of compelling arguments to the contrary from paleoanthropological discoveries in Europe, Asia, and after 1925 in South Africa too.

One plausible explanation is that theories are the filters through which facts are interpreted as Popper (1959b) said. The reason why the English authorities...
adhered to wrong models combines the fatal misinterpretation of the Piltdown hoax with wishful thinking and cultural bias (Spencer 1990a).

The background of the Piltdown man forgery has been analyzed and described in many ways (Spencer 1990a, b). The most plausible explanation why the *Eoanthropus dawsoni* hoax was so successful is that it seemed to provide proof for a missing link between apes and humans, using a mix of plesio- and apomorph characters. Especially, the primitive jaw and dentition made *Eoanthropus* a more suitable intermediate candidate than *Pithecanthropus*. Even after the discovery of *Australopithecus* at Taung in 1924 and the excavation of the first *Sinanthropus* skull from Zhoukoudian (Chou-kou-tien) shortly thereafter, Keith (1931) hypothesized that the Piltdown type arose from the main ancestral stem of modern humanity.

At that time, prominent British anthropologists, such as Smith Woodward, Keith, and Elliot Smith, were fixed on a European origin of humankind and were absolutely in opposition to models of Asian and African origin. The expected phylogenetic sequence was that the cerebralization antedated the changes of the viscerocranium. As the plesiomorph jaw and the apomorph brain of *Eoanthropus* complied with this expectation, it fitted perfectly into a scheme that was in fact wrong.

It took more than 40 years until J.S. Weiner, Sir Kenneth Oakley, and Sir Wilfrid Le Gros Clark jointly exposed the hoax, although there was much skepticism and rumor earlier. Whoever the players were in this black mark in science, they were aware of the attractiveness and fascination of fossils, the rare resources that help to decipher our place in nature, and they obviously knew about the public appeal (Stringer and Gamble 1993; Walsh 1996; Weiner and Stringer 2003; overview in Harter www; Turritin www). The interpretation of the Piltdown fossil as a human precursor was partially responsible for the vehement dismissal of the first *Australopithecus* from South Africa. Dart’s interpretation of the Taung child as missing link between ape and man yielded a storm of controversy (Tobias 1984). As Trinkaus and Shipman (1993 p 206) put it: “The entire scientific coterie of Britain believed in the fossils without hesitation.” This is remarkable insofar as Dart’s discovery matched the prophecy of Darwin (1871 p 202): “It is, therefore, probable that Africa was formerly inhabited by extinct apes closely allied to the gorilla and chimpanzee; and, as these two species are now man’s nearest allies, it is somewhat more probable that our progenitors lived on the African continent than elsewhere.”

To the extent that these and other indications for an extra-European “cradle of humankind” were deliberately ignored, the Piltdown case is a telling example of cut and dried opinions. Small wonder that the scientific output of paleoanthropology during the first decades of the last century was very heterogeneous and confusing.
and more redolent of stagnation than progress. The evolutionary biology at those times was characterized by Mayr as “chaotic” (Tattersall 2000a p 2).

First, even at the beginning of the twentieth century, Darwin’s principles were widely misunderstood by anthropologists, who persisted in orthogenetic biological thinking or insisted on the theoretical split between natural sciences and humanities. Paleoanthropological theory and methodology were still in statu nascendi, judging from the literature of the time (Klaatsch 1899; Hrdlička 1914; Werth 1921; Weinert 1928; Wiegers 1928; Abel 1931; Hooton 1931; Keith 1931; Le Gros Clark 1934).

Second, the rediscovery of Mendel’s work in 1900 demonstrated that new hereditary variation, i.e., mutation, occurs in every generation and every trait of an organism. The founding of genetics at the beginning of the twentieth century gave tremendous support to Darwin’s theory and removed the objections to his postulates. However, the effects of genetics and population genetics were felt less in paleoanthropology than in the biology of recent populations, and especially in aberrations like typological social biology, ethnogeny, and race typology. In Germany, social Darwinism and fatal concepts of hereditary and race dominated biological and medical research on living people. Paleoanthropology was of only minor interest, while the aim of anthropology was defined in the National Socialist area or “The Third Reich” “... der deutschen Volksgemeinschaft zu dienen” (Reche 1937; see further Zmarzlik 1969; Gould 1983; Müller-Hill 1988; Seidler and Rett 1988; Weingart et al. 1988; Zängl-Kumpf 1992; Hoßfeld and Junker 2003; Junker 2004; Hoßfeld 2005a, b).

Third, various approaches to explain the process of hominization later on turned out to be politically highly incorrect: e.g., Kollmann created in 1885 the term “neoteny” suggesting that humans evolved from pygmies who had simply retained juvenile features during size increase (Kollmann 1902). The basic idea was that pygmy progenitors probably arose from juvenile apes that had lost the ancestral tendency to regress. Bolk (1926) argued in a long series of papers that man evolved by retaining the juvenile features of his ancestors. His “fetalisation hypothesis” influenced evolutionary thinking on human origins and formed expectations of the appearance of transitional species. Bolk’s theory was highly criticized and later on rejected by Starck (1962) because it was built on flawed arguments and a misinterpretation of Darwin’s principles. Actually similar questions still resound in the current so-called evo-devo-discussion, e.g., the evidence overwhelmingly suggests that neoteny, the retention of juvenile characteristics, was one of the most important processes involved in the origin of *H. sapiens* (Mingh-Purvis and McNamara 2002; Chapter 3 of this volume).

Fourth, the discovery of numerous Neanderthal skeletons (Table 1.1) caused new arguments in the discussion of gradualism versus continuity. Boule’s monograph evicted the Neanderthals from our family tree, although some outstanding
early twentieth-century paleoanthropologists, like Aleč Hrdlička, argued for gradualism, a controversy that continues to this day (see later).

Finally, the non-European fossils from, e.g., Java, China, and South Africa could have been a strong stimulus for a wider view of human origins, but the prejudice of the leading British scientists crushed innovative hypotheses, and the critical skepticism on non-European roots of humankind due to eurocentristic perspectives and the fatal misinterpretation of the Piltdown man resulted in a stagnation of paleoanthropological theories (Dennell 2001). For this reason, the period after Darwin till 1930 could aptly be named—as Dennell (2001 p 52) comments—the “Age of Prejudices” as European (and North American) perceptions of nonwhites is concerned. The same author goes on to say: “... it is depressing to realize how much of what was written on human origins before WWII was little more than prejudice masquerading as science, it is impossible to understand the study of human origins without reference to these prejudices” (Dennell 2001 p 51). The reader is strongly recommended to read Dennell’s review (see also Hoßfeld 2005b).

1.4 Paleanthropology and politics: three symptomatic events

The misapplication of the Darwinian biological theory known as social Darwinism has been intensively discussed in another context (Mühlmann 1968; Zmarzlik 1969; Altnner 1981a, b; Müller-Hill 1988; Hofstadter 1995; Hawkins 1997; Dickens 2000; Junker 2004; Hoßfeld 2005b). It is well known that this biological ideology became highly influential after the World War I and especially during the period of National Socialism in Germany. That paleoanthropology was no free zone of research stems from different reasons: first, because paleoanthropology was a subject of the highly politically involved anthropology; second, because racial thinking and racist theory were interwoven with all aspects of daily life (Bowler 1976; Stepan 1982; Bowler 1986, 1988, 1996, 1997, 2001; Vogel 2001). The following three symptomatic cases are discussed to exemplify pars pro toto and exemplarily the impact of fascistic ideology on paleoanthropology during the “Third Reich” in Germany.

First, that archiological and paleoanthropological research was not spared by the ideology of the national socialists is documented, e.g., by the fact that the Neandertal-Museum, which had been inaugurated on May 1, 1937, was closed by order of the Reichsleiter für Vorgeschichte, Reinertz, on March 3, 1938. The arguments were that the Museum, which should demonstrate “... Deutsche Urgeschichte, soweit sie mit dem Neandertal in engster Beziehung steht,” did not fulfil the evaluation of an NS-commission (Beckmann 1987).
Second, even more inimical to the development of paleoanthropology during the Nazi era was the fact that the most outstanding German paleoanthropologist at that time, Franz Weidenreich (1873–1948), lost his *venia legendi* at the Johann Wolfgang Goethe University due to the persecution of the Jewish population. His emigration to the USA was an irreplaceable loss for anthropology in Germany. Since he was involved in research on the largest *H. erectus* sample from a single locality, Zhoukoudian, paleoanthropology in Germany lost a vital contact with the international scientific community. Thanks to Weidenreich (1943), there are brilliant documentations, casts, and descriptions of the “*Sinanthropus*”—skulls which were lost during an attempt to ship them to the USA (Shapiro 1974), and—equally important—he is viewed as the founder of the “multiregional theory of human evolution” (Wolpoff and Caspari 1997; Wolpoff 1999).

Third, it must be mentioned that during World War II, the first edition of Gerhard Heberer’s compendium “*Die Evolution der Organismen*” appeared (Heberer 1943). The anthropogenetical contributions deal with comparative anatomy (v. Krogh), paleontology (Gieseler), ethology, and archeology (Weinert). In the view of the scientific historians Hoßfeld and Junker (2003) and Hoßfeld (2005b), the chapter authored by Otto Reche is the only one that takes the model of synthetic Darwinism into account. There is full agreement with the following overall assessment: “...[es] handelt sich über weite Strecken um vergleichende Untersuchungen zur Stammesgeschichte der Menschheit, wie sie bereits im 19. Jahrhundert angestellt wurden, ergänzt durch neuere Daten aus Serologie und Paläontologie” (Hoßfeld and Junker 2003 p 107). The biological impact on paleoanthropology was minor, as long as in practice fossil discoveries came into the literature through collaboration between the archeologists who excavated them and the anatomists who described them. Foley (2001 p 6) states: “Archeologists and professors of anatomy seldom made a rich cocktail of Darwinian theory.” In general, the descriptive casuistic and more or less narrative approaches in paleoanthropology hold true for the period under discussion and for early postwar times, in Germany as well as in other countries (Tattersall 2000a; Foley 2001). The period leading up to World War II had seen the emergence of the evolutionary synthesis, but not until the 1950s did the innovative biological principles and methods begin to inform the paleoanthropological science too (Delisle 1995; Hoßfeld 1997, 2005b; Jahn 2000; Tattersall 2000a; Foley 2001; Corbey and Roebroeks 2001b; Hoßfeld and Junker 2003; Junker 2004) (Figure 1.6).

The selected examples given here demonstrate that social and political reasons far removed from paleoanthropology are important. Dennell (2001 p 45) is right when remembering “... that paradigmatic shifts in palaeoanthropology occur in response to a wider world, and are not wholly dependent on
internal evidence or individual personalities alone.” As Dennell demonstrated very convincingly, there are strong correlations of the shift of paleoanthropological interest from Asia to Africa, first with the transition from colonialism to independence in both Asia and Africa, second with the replacement of Europe by the USA as the dominant influence in paleoanthropology, and finally with the change from paleoanthropological narration to theory-guided analysis and explanation of behavioral changes and adaptations in the past.

1.5 Diversification of anthropology in the second half of the twentieth century

1.5.1 Early post-World War II period

The principal architects of the evolutionary synthesis mentioned previously gained more and more influence in World War II and postwar times, and their ideas shaped the field of biological anthropology including paleoanthropology (Tattersall 2000a; Foley 2001; Junker 2004; Hoßfeld 2005b). Although the fossil record had steadily increased, it was still a challenge to reconstruct the raw outlines of human evolution from the tiny catalog of human skeletal remains. There was tremendous progress as the hominin status (at that time taxonomically
tered hominid) of the small-brained, bipedal australopithecines became accepted due to the new results from fossils from Kromdraai Cave, excavated by Robert Broom in 1938, and further remains from Sterkfontein and Makapansgat, which were dug up in 1947. The diversity of the australopithecine taxa became further obvious from the megadontic *Paranthropus* from Swartkrans. The phylogenetic tree of our origins seemed to be quite simple. However, as the dating of known specimens was limited to the relative timescale “older than/younger than,” and as the techniques of absolute dating were unknown, there was a lot of uncertainty in the calibrations. Still the overall picture was a stepwise adaptive evolution from primitiveness to high-order hominids/hominins with modern shaped bodies and cultural skills. The evolutionary ladder reached from the gracile and robust australopithecines, i.e., very ape-like species, to the *Pithecanthropus* and *Sinanthropus* species. These had been lumped with the European *H. heidelbergensis* in a single species, *H. erectus*. This simple gradualistic model regarded the Middle Pleistocene “Java man,” “Peking man,” and the “Mauer man” as intermediate stages between the early taxa from Africa and the later Neanderthals, a well-documented fossil human group from late Ice Age sites in Europe and western Asia. Little wonder that in this confusion paleoanthropologists welcomed Mayr’s and Dobzhansky’s simplifying message that only one kind of hominid (new systematic: hominin) could have existed at any time and that virtually all developments in human evolution since Java man had taken place within the single, albeit variable, species *H. sapiens*. Tattersall (2000a p 3) suggests that Dobzhansky was influenced “by his newly arrived New York neighbor Franz Weidenreich, nowadays hailed as the father of ‘multiregional continuity’.”

Mayr took the position that at the most three successive species could be discerned within the genus *Homo*: *H. transvaalensis* (the australopithecines), *H. erectus*, and *H. sapiens* (including the Neanderthals). Few paleoanthropologists followed these pronouncements in all their details; however schemes of hominin evolution routinely came to incorporate the synthesis’ basic assumptions, whereby evolutionary change consisted simply of the gradual modification of lineages, usually no more than one, over long spans of time. Human evolution thus became the story of a long, single-minded struggle from primitiveness to perfection (Tattersall 2000a pp 1-16; contra Foley 2000). Successively there arose different problems from Mayr’s simplified model:

First, the evolutionary model was in contradiction to the mosaic pattern of the erroneously ancient, heavily encephalized Piltdown man. This problem disintegrated when in 1953 Piltdown was declared a hoax by authorities at the British Natural History Museum (Spencer 1990b). Second, the credibility of paleoanthropological results was severely flawed due to arbitrary taxonomic approaches. For this reason, there was a genuine need for the revision of the
overabundance of species and genus names, which had been applied liberally more or less without a taxonomical concept to hominid fossils. The taxonomic revision of the hominid/hominin sample asked for a strict taxonomic concept (Washburn 1953; Waegele 2000; Wiesemüller et al. 2003). Third, the uncertainty of the temporal allocation of fossils still reflected the absence of absolute dating techniques (Bishop and Miller 1972). In sum, it became more and more obvious that there was tremendous need for a new and precise strategy of physical anthropology within the frame of a revised synthetic theory of evolution (Washburn 1953; Cartmill 1990; Bowler 1997).

In the immediate postwar period, there arose a body of theory that swept away a host of conflicting notions about the nature of the evolutionary process. The elegantly simple concept stated that all evolutionary phenomena could be ascribed to a single mechanism: the gradual change of genes and gene frequencies within lineages of organisms under the guiding hand of natural selection (Cartmill 1990). The innovative population genetic approach was an important one for the field of paleoanthropology too as this was the time when the discipline absorbed the theoretical underpinnings that continue to influence it to the present day (Wuketits 1978; Vogel 1983; Foley 1987; Martin 1990; Jones et al. 1992; Delisle 1995; Tattersall 1995, 2000a, b; Foley 2001; Ruse 2005).

### 1.5.2 New strategies, concepts, and challenges in physical anthropology

In the early 1950s, there started an intensive discussion on the strategy of physical anthropology, i.e., the body of scientific theory and techniques with which it attacks its problems. Washburn (1953) was one of the protagonists of a new conception which was formulated in the new version demonstrated in Table 1.2. The main step was to reduce the speculative and narrative part of physical anthropology in favor of a thorough hypothesis testing. Cartmill (1990 p 189) puts it this way: “No doubt, people are different from the apes; but it is our job as scientists to explain those differences. Explanation, as opposed to mere storytelling, has to invoke law-like regularities connecting causes and effects.” This then was the challenge facing the evolutionary biological sciences (Popper 1968). Of greatest importance for the renewal of physical anthropology were the rejection of typological concepts and an increased interrelationship between the different parts of anthropology. The change from descriptive studies to the investigation of process and behavior brought about the integration of the problems of human evolution in the vast scientific field of mammalian evolutionary biology. Solutions to problems consequently followed, on the one hand
from paleontology, primatology, genetics, population genetics, and diverse medical sciences and on the other hand from the study of archeology and ethnology.

The great challenge of human evolutionary biology became the cultural factor as adaptations, human migrations, mating systems, population densities, diseases, and human ecology all became factors seen as essential to the explanation of our special human way of life (Washburn 1953; Vogel 1966; Osche 1983; Foley 1987). Washburn’s (1953 p 726) prognosis was: “If we would understand the process of human evolution, we need a modern dynamic biology and a deep appreciation of the history and functioning of culture. It is this necessity which gives all anthropology unity as a science.”

The recognizable post–World War II shape of paleoanthropology resulted from the belated acceptance of neo-Darwinian principles of evolutionary biology,
which were successively constituted in the 1930s and 1940s and that unified evolutionary biology under a single roof, sweeping away a huge package of mythological narrative thinking (Henke and Rothe 2006). Delisle (1995 p 217) suggested: “… that the evolutionary synthesis directly influenced on human paleontology [during the decade 1950–1960] every day practitioners in human paleontology almost solely through the general concepts and methods of the new systematics. Instead of being only a common core shared by a host of disciplines, the evolutionary synthesis should also be defined by the extent to which that core has been guiding current research in any one field.”

But, was the Modern Synthesis a real step forward in the right direction? Tattersall (2000a p 2) judges this step from an overcritical point of view and comments: “Sadly, however, the Synthesis was doomed to harden, much like a religion, into a dogma: a dogma whose heavy hand continues to oppress the science of human origins a half-century later.” He gives many arguments for this judgment, e.g., Dobzhansky’s lumping of the fossil hominids, with the conclusion “… that there existed no more than a single hominid species at any one time level” (Dobzhansky 1944 pp 261–262); further there was Mayr’s claim that humans did not speciate (Mayr 1950), a position which opened for later proponents the so-called “single-species-hypothesis.” Finally there came the controversy on “stasis” versus “punctuated equilibria” (Eldredge and Gould 1972). Tattersall (2000a p 5) complains that paleoanthropology was laggardly: “Slow to absorb the principles of the Synthesis, palaeoanthropology has been equally slow to augment these principles with recognition of the multifarious complexities of the evolutionary process.”

Is paleoanthropology really a discipline apart from the mainstream of biological thinking, and has the Modern Synthesis really shadowed the scientific work of paleoanthropologists? During the last 50 years, the last vestiges of the so-called “step ladder” model have been successfully refuted. While the unilinear and anagenetic models vanished from discussion, it became increasingly obvious that the process of human evolution is convincingly shown with multiple species, cladogenesis, and adaptive radiations, as well as the mechanisms and the process of the punctuated equilibrium model. Our current perspective is based on the broad acceptance of multiple species (slogan: “no tree but bushes”) and complexity of hominin diversity form (Cartmill 1990; Henke and Rothe 1994, 1999b, 2003).

There are reproaches against the Modern Synthesis as an obsolete theory which was uncritically used to give support for unilinealism, but not all recent protagonists of evolutionary thinking agree with the dichotomous equation “synthesis = unilinealism” and “multiple species = macroevolution.” Foley’s opposing arguments center on the point that paleoanthropology remained “… in fact […] blithely innocent of most theoretical issues” (Foley 2001 p 5). I incline
toward Foley’s (2005) opinion that the anagenetic models of the 1960s and 1970s owed, firstly, more to presynthesis notions of progress than to a model of adaptive fine-tuning and secondly, that Weidenreich’s position often reflected orthogenetic thinking rather than neo-Darwinian models of evolution (Foley 2001 p 6).

Concerning the first point, I would cite Vogel’s (1983 p 225) biological perspectives of anthropology and the so-called theory-deficit of the physical anthropology in Germany. He quotes Washburn (1953), who pleaded that the “... application of a constituent, experimentally verified, evolutionary theory is the first task of the physical anthropologist.” One should remember that Vogel’s paper was presented in 1981, which means that paleoanthropology and in a wider sense physical anthropology remained behind to other evolutionary sciences (Spiegel-Rösing and Schwidetzky 1982). Although paleoanthropology was not the foremost field of anthropological research in Germany, there appeared new editions of Die Evolution der Organismen (Heberer 1959, 1967–1974) and the textbook Menschliche Abstammungslehre (Heberer 1965a, b). In spite of these and other prominent publications in Germany in the 1960s and 1970s (Kurth 1962, 1968; Heberer 1968b; Hofer and Altner 1972; Kurth and Eibl-Eibesfeldt 1975; overviews in Hoßfeld 1997, 2005; Henke and Rothe 2006), there remained a theoretical vacuum in anthropology, and anthropology seemed here—as well as in other European countries—much more fossil-driven than hypothesis-guided. Cartmill (1990, p173) claimed in the early 1990s: “Paleoanthropology should aim at increasing its theoretical content by reducing the list of qualitative human uniquenesses—and eliminating it altogether if possible.” The evaluation of the scientific reasons that perpetuated inadequate evolutionary approaches in paleoanthropology and caused the complacency with insufficient models is still incompleted. Whether “... the Synthesis was doomed to harden much like a religion, into dogma as Tattersall claims (2000a p 2), contra Foley (2001), is a continuing issue; but most can agree with the statement that paleoanthropology was not explicitly theoretical but was descriptive and in part excessively narrative (Bowler 1996, 2001; Foley 2001; Ickerodt 2005).

In contrast to the European situation, paleoanthropologists in the USA have traditionally been trained as physical and cultural anthropologists. This caused a different approach to the research in human evolution; in the traditional European system as a rule archeologists dug up the fossils and they themselves or anatomists—not physical anthropologists—described them and perpetuated the problem. The simplicity of the narrative approaches also hampered progress. The idea of human uniqueness was emphasized (Cartmill 1990) and hominin fossils were treated casuistically. Foley (2001 p 7) confesses that it was “... frustration with the combination of an absence of evolutionary theory in human evolution and assumptions about human uniqueness that led me to

Historical overview of paleoanthropological research
His sophisticated approach tries to explain the process of human evolution and the human adaptive strategy as intersection of the biological categories to which hominins (in Foley’s original hominids) belong (Figure 1.7). Although most hominin diversity can be explained by evolutionary changes caused by geographical–climatological factors,

there is a vast explanatory field within the life sciences, particularly comparative primatology, sociobiology, paleoecology, and paleogenetics. The multidisciplinarity of paleoanthropology is demonstrated in Figure 1.8, however, without a detailed special ranking concerning the importance of the cooperating disciplines. The preference for cooperation naturally depends on the paleoanthropological
problems that have to be solved, but it should be remembered that inter-, multi-, and transdisciplinarity is a learning process and an everlasting challenge for science (Mittelstraß 1989; Drilling 1992; Eggert 1995; Porr 1998; Henke 2006).

The last half-century has witnessed a dramatic improvement in our understanding of the process of human evolution, due to new approaches and techniques as well as a tremendous increase in the fossil record (Andrews and Franzen 1984; Franzen 1994; Henke and Rothe 1994; Ullrich 1995, 1999; Johanson and Edgar 1996; Hartwig 2002; Schwartz and Tattersall 2002, 2003). Profound knowledge of the relationship between form and function has come from innovations in mechanical engineering, light microscopy and REM, 2D- and 3D-tomography as well as from multivariate statistics (Grupe and Peters 2003; Zollikofer and Ponce de Leon 2005). Furthermore, evolutionary and developmental morphology (Mingh-Purvis and McNamara 2002) and physiology (Martin 1990) has contributed to a better understanding of form–function complexes (Ciochon and Corruccini 1984; Oxnard 1984; Aiello and Dean 1990; Anapol et al. 2004; Ross and Kay 2004). Hennig’s Phylogenetic Systematics (Hennig 1966, 1982, 1984), which was first published in German in 1950 without gaining much attention (Hennig 1950), revolutionized phylogenetic discussion in concert with tremendously increased skills in taxonomy and computer techniques (Rieppel 1999; Waegele 2000; Wiesmüller et al. 2003).
With the improvement of absolute dating techniques (e.g., radiocarbon and other isotopic calibrations) and in relative dating by faunal complexes, the chronological pattern of human evolution was more precisely observed, and it became seen through the application of “molecular clocks” that the branching of the hominin line coincided with the aridification of the East African Rift Valley (Bishop and Miller 1972; Howell 1978; Magori et al. 1996; Bromage and Schrenk 1999).

The more that research on human evolution concentrated on the African continent, the more successful those paleoanthropologists with a licence to dig became, especially as they extended their campaigns to Miocene as well as to Pli- and Pleistocene strata. Leakey’s luck (Cole 1975; Isaac and McCown 1976) at Olduvai Gorge—which had been discovered by the German neurologist Wilhelm Kattwinkel in 1911 (Glowatzki 1979) and was successfully explored for the first time in 1913 by Reck (1925), as well as that of his family members in Koobi Fora and diverse other East African sites—has resulted from tremendous efforts (Leakey and Leakey 1978; Grine 1988; Wood 1991; Tobias 1991; Walker and Leakey 1993). Beside the activities of the Leakey family, there should be mentioned the successful expeditions of Francis Clark Howell in Omo, Glynn Isaac in Olorgesailie, and of course the famous Afar Research Expedition (Johanson and Edey 1980; Johanson and Edgar 1996). Finally, the Hominid Corridor Research Project of Timothy Bromage and Friedemann Schrenk in Malawi (Bromage and Schrenk 1999) must be alluded to as well as the activities of Brigitte Senut and Michael Pickford in Tansania (Pickford and Senut 2001) and Brunet et al. (2002) in Chad. Africa has become the “Mecca” of paleoanthropologists. There is little doubt now that Africa was the “cradle of mankind,” just as Darwin proposed.

In spite of the fact that the “fossil hunting” has mostly been done in Africa, there are many activities in other parts of the Old World allowing us to learn more about the pattern of hominid migration and development. Exciting new fossils and findings from, e.g., Atapuerca (Spain) (Arsuaga et al. 1999), Apidima (Greece) (Pitsios 1999), Ceprano (Italy) (Ascenzi et al. 2000), Schöningen (Thieme 1996), Dmanisi (Georgia) (Bräuer et al. 1995; Henke et al. 1995; Gabunia et al. 1999, 2002; Vekua et al. 2002) and many non-European sites (Delson 1985; Rightmire 1990; Franzen 1994; Johanson and Edgar 1996; Delson et al. 2000; Brunet et al. 2002; Schwartz and Tattersall 2003), and the astonishing fossils from Flores (Indonesia) (Brown et al. 2004) demonstrate that paleoanthropology is a field of research with never-ending surprises and new perspectives. No doubt, the half-life of our theoretical models is very short, but there has undoubtedly been enormous progress. Beside the paleontological fieldwork, which has also produced valuable data for the reconstruction of the ecological
niches of our ancestors (Bromage and Schrenk 1999), the research field of primatology has become increasingly important for anthropological modeling (Martin 1990; MacPhee 1993; Fleagle 1999; Groves 2001). The paradigm of behavioral ecology and sociobiology has shaped our hypotheses on food choice, foraging patterns and food detection, as well as on food sharing and intra- and intergroup relations. Studies on the evolution of social behavioral systems, kin selection, intersexual and intrasexual selection, cognitive abilities, tool using and tool making, Machiavellian strategies, competition, coalitions and alliances, that is on the total complexity of social systems in primates, especially in apes, have become essential for paleoanthropological modeling (Henke and Rothe 2003; Henke 2003a; Rothe and Henke 2005). Beside the primatological field studies, which have given us a totally new view on the cultural capabilities of nonhuman primates, there is much to learn about our brains and the development of language from all kinds of laboratory research [e.g., molecular biology: O’Rourke et al. (2000), Enard (2005), psychobiology: Tomasello (1999)].

Still, the “old questions” in paleoanthropology (v. Koenigswald 1958) remain unsolved and valid. One hundred and fifty years after the excavation of the name-giving fossils from the Neander Valley, near Düsseldorf in Germany, the “role of the Neanderthals” is the subject of intense discussion (Spencer 1984; Stringer and Gamble 1993; Henke and Rothe 1994, 1999b; Tattersall 1995; Krings et al. 1997; Wolpoff 1999; Relethford 2001; Finlayson 2004). Also debated are the Out of Africa models (Bräuer 1984; Bräuer and Smith 1992; Wolpoff 1999; Relethford 2001; Finlayson 2004). Maybe the humorous definition “humans are animals who wonder intensively and endlessly about their origin” is the most appropriate one for our species. We are in an age of tremendous progress in paleoanthropological research and knowledge, which hopefully is evident in the contributions of this handbook.

1.6 Final remarks

The preceding survey demonstrates that, compared with other biological sciences, progress in paleoanthropology was slow for most of the last century. The reason for this is multifaceted and still under discussion (Tattersall 2000a; Dennell 2001; Foley 2001; Corbey and Roebroeks 2001b). One important problem leading to slow progress was a descriptive and nonanalytical approach due to theoretical deficits. Innovative approaches and the positioning of paleoanthropology within a complex research strategy of evolutionary biology integrating all facets of comparative primatology, behavior ecology, sociobiology, molecular and
population genetics (Martin 1990; Jones et al. 1992; Jobling et al. 2004), as well as archeology (Klein 1989; Gamble 1999; Klein and Edgar 2002), archeometry (Herrmann 1986, 1994), and earth sciences (Isaac and McKown 1976; Foley 1987; Bromage and Schrenk 1999) have led to a change. Within a broadly based scientific field and a consequently theory-guided empirical approach, paleoanthropology has become during the last decades a “mature” science. The integration of paleoanthropology into the wider set of biological sciences and the system theory of evolution is the road map paleoanthropologists should follow to achieve reasonable and credible scenarios of the past. Paleoanthropologists should be aware of the principal aims of scientific work (Popper 1983; Mahner and Bunge 2000) to avoid the pitfalls of a narrative, storytelling, as well as fossil- and journalism-driven science (Cartmill 1990; Tattersall 1995; Franck 1997, 1998a; White 2000; Schrenk and Bromage 2002).

With the principal and methodological suppositions of the biological and neighboring sciences in mind, paleoanthropologists should be aware of science history too, or, in the words of Theunissen (2001 p 147): “That ‘history matters’ is perfectly obvious if it is taken to mean that the present cannot be understood without reference to the past.” Although this statement seems to be trivial, there is a dilemma which Foley (1987) mentioned: there is no doubt that the past was a “foreign country” and that our forerunners did things differently there. The challenge of paleoanthropology is to improve our scientific methodology, to learn more about us and our origin, to reach a biological and sociobiological self-conception (Vogel 2000). The historicist approach may give rise to reflexive doubt. But Dennell (2001 p 64) is right when he says: “Whilst we might like to think that palaeoanthropology is a discipline that unifies humanity and helps combat racial, sexist, and other types of prejudice simply because of its focus on the origins of humankind, we should not forget it did the opposite for at least the first half of the 20th century.”

The confidence of being on the right road raises the risk of complacency. And herein lies the essential argument that history really matters, that one should never be too comfortable for too long a time with an idea. What is really needed is a real and intensive dialogue between the many disciplines, which cooperate to unravel the process of human origin. Returning to the introductory question of whether science history matters within this canon of disciplines, the conclusion must be that history forms a constitutive part of present day research. The history of paleoanthropology teaches us, in all facets and details, that the reconstruction of our origin is a real challenge; McHenry (1996 p 86) puts it: “One needs to make the best of our tiny sample of life in the past, to be open to new discoveries and ideas, and to enjoy the pleasure of learning and changing.”

2 Evolutionary Theory in Philosophical Focus

Philippe Huneman

Abstract

This chapter surveys the philosophical problems raised by the two Darwinian claims of the existence of Tree of Life and the explanatory power of natural selection. It explores the specificity of explanations by natural selection, emphasizing the high context dependency of any process of selection. Some consequences are drawn about the difficulty of those explanations to fit a nomological model of explanation, and the irreducibility of their historic-narrative dimension. The paper introduces debates about units of selection, stating the compelling force of genic selectionism but highlighting some critiques. It then addresses the limitations of selectionist explanations: the compared status of selection, drift, and phylogenetic inertia are investigated, and the debates over adaptationism are presented, with the aim of defining the varieties of adaptationisms as research programs. In order to assess the scope of natural selection, the chapter addresses weak and strong challenges to the Synthetic theory of evolution both from paleontology (punctuated equilibria, Gould’s contingency thesis) and the evolutionary theory of development. We finally sketch some consequences of evolutionary theory concerning philosophical questions about human nature, on the basis of the hypothesis of the universality of selectionist explanations: this part deals mostly with epistemology and psychology.

2.1 Introduction

The theory of evolution, from Darwin to the Modern Synthesis formulation, provided a framework of explanatory strategies to explain diversity and adaptation in the living realm. Considered on a large scale, Darwinian science advanced and justified two main claims: the Tree of Life, meaning that all the extant living species are always historical results of common descent, and the Selection hypothesis, meaning that one of the most important mechanisms to account for those transformations is “natural selection.” Hence, it added to the ancient life sciences
a new *explanandum*, e.g., phylogenesis, and a new *explanans*\(^1\)—natural selection—which is also an explanatory resource for more traditional kinds of problems.

Of course, the consequences of the two main Darwinian claims were not recognized immediately; people were too much concerned by the two metaphysical issues of evolution versus creationism, and of the animal origins of man. It took a little less than a century to acquire the historical distance that enables one to rightly appreciate the novelty of Darwinism and this happened with the Modern Synthesis. For the Synthesis, population genetics has a central status within evolutionary thinking: historically, two of the founders of the synthesis, Fisher and Wright, were population geneticists, and some fundamental statements of evolutionary biology are enunciated in population genetics (Fisher’s theorem, Hardy–Weinberg equilibrium, etc.); conceptually, the definition of evolution, as a change of the gene frequencies in the gene pool, lies in the field of population genetics. This essential feature of the theory was not conceivable in the time of the first Darwinians, since the gradualist view of transformism seemed to contradict the discontinuous vision of organisms as mosaics of traits that Mendelian genetics had presupposed. It is often and truly said that neo-Darwinism unified Darwin and Mendel, thereby superseding such an apparent conflict.\(^2\) Weissmann, by separating soma and germen and advocating that there was no transmission of the acquired characters, gave a clear meaning to the difference between Darwinism and Lamarckism and allowed his followers to regard only what is in the germen as the substrate of evolution, enabling the future integration of genetics within evolutionary biology. Moreover, Weissmann proved impossible the theories of heredity and variation maintained by many biologists and Darwin himself, according to which hereditary traits could be produced within the individual organism’s cells and flow continuously from them. It then became possible for geneticists to propose mechanisms of heredity and variation in which the Darwinian theory of natural selection had only to assess the facts of heredity and variation, without being in principle committed to any theory of heredity (even if that was what Darwin actually did).

In order to grasp the new kind of epistemological problems brought by the two Darwinian contentions, it is quite useful to recall the features of the earlier biology that they replaced. The main explanans of diversity and adaptation before

---

1. In the usual vocabulary of the philosophy of science, *explanandum* means what is to be explained, whereas *explanans* means what explains the *explanandum*.
2. For an account of the conceptual transformations which led from Darwin to neo-Darwinism through the successful synthesis of Mendelian genetics and Darwinian hypothesis, see Gayon (1998).
Darwin was, as we know, the divine design, although other hypotheses were being proposed more and more often, especially the evolutionary theory of Lamarck, which was adopted by Geoffroy Saint Hilaire and many morphologists at the beginning of the nineteenth century. This design was invoked to account for some *prima facie* teleological features of the living world, such as the fine adaptation of organisms to their environment, or the fine tuning of the mechanisms of biological function, or, in the end, the proportions of individuals in various species and the geographical relationships between species. The divine design yielded simultaneously the *individual designs* of organisms, unlikely to be produced by the mere laws of physics, and the *design of the whole nature* that Linnaeus called the “economy of nature.” The Selection hypothesis gave a powerful explanation of those two designs, since adaptations of organisms as well as distributions of species in a population were likely to be understood by appealing to the process of natural selection (even if other mechanisms like Lamarckian ones were also used by the first Darwinians\(^3\)). Since the result of such a process is a Tree of Life, biologists justify the striking similarity of forms between different species of the same genus, or even different genera of the same family—this fact being an immediate result of the common descent of different members of a same taxon.

However, the rise of Darwinism did not mean a total shift of the relevant questions and tools in biology. Rather than deleting centuries of research in the science of life, Darwinism gave a new and coherent meaning to some admitted facts and descriptions. Instead of rejecting teleology outside science, it provided a way of interpreting teleological phenomena so that they did not depend on nonnaturalistic presuppositions, such as hidden intentions of the organisms or their creator; it kept the result of the traditional taxonomist’s effort and conceived the systematic proximities in the classification of species as historical affiliations, as Darwin himself noticed at the end of the *Origin of Species* (even if, of course, the Darwinian views raised new questions and permitted new criteria and methods for systematists (Ghiselin 1980)).

So, evolutionary theory appears to us as the most successful and integrative framework for research strategies in biology. Before investigating the details of the epistemological challenges raised by the two Darwinian claims, it is therefore useful to situate evolutionary theory within the whole of biology. Here, Ernst Mayr’s conception of explanation in life sciences will be of some help. In effect,

---

\(^3\) On the progressive extension of Darwin’s theory, and all the slight nuances that made it very different from what we use now and the sharp picture here drawn, see Ghiselin (1969), Ospovat (1981), Ghiselin (1969) and Bowler (1989). Ospovat emphasizes the conditions for Darwinism in the work of morphologists like Geoffroy and Owen.
Mayr distinguished two kinds of causes as different answers to the question “why” (Mayr 1961). When asked: “why does this bird fly along the seashore to the south?,” you can answer by pointing out its physiology, respiratory system, the diverse pressures on its wings, and the streams of air around it: this indicates the proximate causes of the bird’s flight. But you can also answer by emphasizing that the way it takes to go to the south curiously corresponds to the old demarcation of the continents, and you will understand that this is a result of natural selection acting on this species of bird to improve its time of migration. This is the ultimate cause of the bird’s trajectory. Notice that the first causes concern exclusively one bird, and each bird is concerned by them in the same way, meaning that they are generic causes. On the contrary, the ultimate causes collectively concern the ancestors of this bird and not the bird itself.

Notice also, and this will be of importance for all epistemological considerations, that the two kinds of causes do not answer exactly the same question: the former answers the question “why does the bird fly along the seashore (rather than being unable to fly)?”, whereas the latter answers “why does the bird fly along the seashore (rather than somewhere else)?” This distinction, highlighted in another context by Sober (1986), means that the two kinds of causes are embedded in different explanatory strategies. As Mayr would remark, a complete biological explanation of a phenomenon makes use of all those strategies. And the two kinds of causes correspond to two kinds of biological discipline: on the one hand, as sciences of the proximate causes we have molecular biology, physiology, endocrinology, etc. while on the other hand, as sciences of the ultimate causes we have all those disciplines belonging to evolutionary biology: population genetics, ecology, paleontology, etc.

Having characterized evolutionary theory as a specific set of research programs within biology, and those programs being defined by the use of the hypothesis of natural selection, we can present some evolutionary problems raised by evolutionary theory. These will concern essentially the nature and the limits of the explanation by natural selection. Thus, I will reveal these two kinds of problems by picking out, in each category, one or two fundamental and currently debated issues. Then I will stress some important consequences of evolutionary biology upon philosophical theorizing about human nature.

We must nevertheless notice that all those issues involve both biological and philosophical considerations. They will sometimes be closer to theoretical biology and the methodology of biology than to philosophy but will sometimes include apparently pure matters of metaphysics that make no difference in empirical science. However, I claim that there is a set of problems raised by evolutionary theory that is of essential interest for philosophy, but that cannot be handled by the traditional means of a general philosophy of science—and that
therefore must constantly appeal to considerations of theoretical biology. The fact that the Modern Synthesis has a unique character compared to other improvements in science (Shapere 1980), is surely one of the reasons for this peculiar status of the philosophical problems raised by evolutionary theory. However, given this special status, authors contributing to the debates are either philosophers of science, like Hull, Sober, Rosenberg, or Kitcher, or sometimes biologists who may have made major contributions to evolutionary biology, like Mayr, Gould, Maynard-Smith, Williams, or Lewontin. Philosophy of biology partly emerged from the dissatisfaction of philosophers of science with the logical positivistic program and their will to find new paths toward unsolved questions, and partly from the need, felt by biologists, of conceptual elucidations of the bases of their practice and of the consequences of their theories.

2.2 Evolutionary biology: its challenges for philosophy of science

2.2.1 What is selectionist explanation?

2.2.1.1 The process of selection and the property of fitness

Natural selection is a process that is expected to take place whenever the following requirements are fulfilled: there is a set of individuals; those individuals reproduce; there is variation among them and those variations are likely to be hereditarily transmitted; due to interaction with the environment, some varying properties provide their bearer with a chance to leave more offspring than individuals who lack such a property.

No matter what the entities are that fulfill those requirements, their set is, from now on, susceptible to be affected by natural selection. For this reason, people have proposed a theory of natural selection of macromolecules to account for the origins of life (Eigen 1983; Maynard-Smith and Szathmary 1995), or theories of natural selection of ideal elements in order to explain cultural evolution (Cavalli-Sforza and Feldman 1981; Boyd and Richerson 1985; Campbell 1990). The methodological problem here is to invoke a process of heredity, which is not as obvious as in the case of genes.

And, reciprocally, when one meets a set of individuals fulfilling these requirements, one can assume that those individuals have undergone natural selection so that their properties are the effects of natural selection (or, more precisely, the fact that they have the properties that they have, and not some other properties, is the effect of selection).
Let us state some characteristics of explanation by natural selection. First, this belongs to what Mayr (1959b) called “population thinking,” e.g., the explanandum has to be or to belong to a class of entities—what we call a population—for otherwise the differential reproductive success that is the result of having or not having a property, which in turn is what is meant by the word “selected,” would not be determinable.

This explanation by selection might be contrasted with what Sober (1984) called “developmental explanation,” namely, an explanation of the property of an individual appealing to the process through which it was acquired. The developmental explanation of the composition of a football team is the sum of the experiences of each of its players; the selective explanation is the choice of the team by the manager, who set a criterion of competence and then evaluated all available football players by this criterion. What is peculiar to selectionist explanation is the fact that there are no determined criteria of admission other than reproductive success.

This brings us to an essential characteristic of selectionist explanation, namely the fact that it is always selection for effects; hence it is blind to causes. No matter whether a red deer reaches reproductive success over his congeners as a result of his higher race speed, or through his visual abilities to detect predators: in both cases, the fact that he leaves more offspring will mean that his genes (among them, the ones bound to the decisive property) will be more greatly represented in the following generation. This sole fact is basic to natural selection and to selectionist explanations. According to a distinction made by Sober (1984), selection of something X (for example the red deer) is always selection for some property A enhancing survival and reproductive success (but of course, other properties, linked with A in X, are also selected of).

If we measure the selective advantage conferred on an individual by its properties, and use the term “fitness” for such a measure, then different properties (different in physical and chemical terms) will be likely to have the same fitness (always measured in a given environment). Thus, two consequences follow concerning fitness. First, fitness is what philosophers of science call “supervenient” on the physical and chemical properties of traits. This means that, if two traits are different, they may have the same fitness or not, but if two traits have different fitnesses, they must be physically or chemically different. Supervenience, so defined, implies “multirealisability,” meaning that a same fitness can be realized by various ontologically different properties and devices (Rosenberg 1978; Brandon 1990; Sober 1993).

---

4 Here, there is no direct reference to the embryological development.
The second consequence is that this property of fitness, since it depends on population-thinking explanatory strategies, has to be thought of as a probabilistic one, hence as a “propension” (Mills and Beatty 1979; Brandon 1990\(^5\)). This has an obvious reason: fitness is indicated by differential reproductive success, hence by the number of offspring. But two different individuals can have the same fitness and nonetheless leave different numbers of offspring. Mills and Beatty used the example of the twins, sharing a same genotype in a same environment, hence having the same fitness; nevertheless, one of them is struck by the lightning while still a young man, whereas the other mates and has six children. Thus, the actual number of offspring cannot represent the fitness; but fitness has to be measured by the expected number of offspring, which is a probabilistic parameter. A given individual may not leave the number of offspring stated in its “fitness.” One can easily see here that, if this were the case, then the fittest individual would be the one who leaves the most offspring, and evolution as the “survival of the fittest” or the reproductive success of the fittest would be a tautology. So, the idea of fitness defined according to a propensionist theory allows us to avoid the charge of tautology recurrently raised against Darwinism.

If fitness is a supervenient property, this entails important consequences for the relationship between biology and the physical sciences. In short, no necessary physical statement can account for biological phenomena involving selection—therefore, fitness—since the same fitness could be realized by other physical matters of facts, laws, and properties. Hence, evolutionary theory supervenes on the physical propositions and theories. But what about the status of selectionist explanations in biology when compared to the explanations in physical sciences?

\subsection*{2.2.1.2 Laws and selectionist explanation}

Here we come across the rather entangled philosophical topic of scientific laws. Physicists state laws of nature. However interpreted, those laws of nature are general statements formulated in the modality of necessity.\(^6\) The usual puzzle in philosophy of science is to find a criterion distinguishing accidental generalities and laws (Ayer 1956). As an answer, Dretske (1977) claimed that laws have to be conceived as relationships between universals. But in any case, laws should support counterfactuals: this means that if some variables are changed within

---

\(^5\) Critique is made in Rosenberg (1982); other recent critiques led to the precision of the propensity definitions (Sober 2001; Ariew 2004).

\(^6\) I leave apart here the difference between empirical and a priori laws.
them, the results should be affected in a regular way. This implies that lawlike generalizations can be used in explanations, whereas accidental generalizations seem not to allow such a use and even less a predictive use. The positivistic account of science viewed explanation as a deductive argument whose conclusion is the explanans, and whose premise sets some laws of nature with some particular statements of facts [the so-called DN account of science: Hempel (1965)].

In a provocative chapter of his *Philosophy of Scientific Realism*, Smart claimed that there are no biological laws, since any law has to be reliable for any individual, e.g., has to be stated in the form “for any X, P(X).” But in evolutionary theory, we only have statements concerning limited sets of entities, like teleost fishes, or more generally, birds in America, or *Equus*. People can forge seemingly law-like general assertions on the basis of such generalizations, like Dollo’s law concerning irreversibility in evolution, or Cope’s law concerning the increasing of size in populations; but they are nevertheless still spatio-temporally situated general statements lacking any nomothetic necessity. Necessity is supposed to hold for any individual of a given kind with no specification of space and time. These regularities fail to explain but merely describe; they are not predictive since they always find exceptions. For Smart, such biological regularities are like the schemata of engineers and are in the same way embedded in laws of physics. Even the universality of genetic code is a generalization on our planet, due to the contingent reason of common ascendance (contingent regarding the code itself), since the same correspondence laws between nucleotides and amino acids are not to be expected on any planet. For Beatty (1997), this contingency of generalized propositions affects the whole of the supposed law-like statements in biology. So the DN account fails to represent evolutionary theory.

The only evolutionary statement that could be a law is, thus, the one enunciating the process of natural selection since it specifies no particular entity. Philosophers debate about the nomothetic status of this principle of natural selection (PNS) (Bock and Von Wahlert 1963; Sober 1984, 1997; Brandon 1996, 1997; Rosenberg 1985, 1994, 2001). Rosenberg argues that the PNS is the only law of biology and relies on Williams’ (1970) axiomatization of the theory, which conceives fitness as an undefined primitive term, e.g., a term which in some definitions, in some contexts, can be given only outside evolutionary theory, in

---

7 Taking a famous example from Goodman, what predictions could I infer from “all the men in this room are third sons” (unless I have some additive information on those men, like: “they are all attending a third sons’ meeting”, etc.)?

8 Rosenberg (1994) also denies that biology has laws in the sense of physical laws since it supervenes on all the physical laws and hence can only pick out disjunctions of laws applied in limited contexts.
another theory. But, even if by convention we say that it is a law, we still face the question of its differences from the other kinds of law.\textsuperscript{9} In effect, unlike physical laws, the PNS does not state \textit{any natural kind} of property such as mass, electric charge, etc. The only property involved in its formulation is fitness, which is a mere supervenient property.

So the PNS becomes the equivalent of a physical law—stated in probabilistic language, of course—only as soon as some physical characters of the properties contributing to fitness are \textit{specified}, a specification which is always context dependent.\textsuperscript{10} For instance, the “optimal shift towards viviparity” described by Williams (1966) in some marine fishes results from a kind of law, since he stated the parameters ruling the selection pressures (density of predators, physiological cost of reproduction); parameters which in turn determine a range of relevant physical properties for selection. Hence, in this case the schema becomes predictive, and we can test it by building experiments in which the values of the variables concerned vary. This idea, however, does not exhaust all biological regularities, principally the aforementioned ones found in paleontology. Thus, recalling the two claims of evolutionary theory concerning both the Pattern and the Process of evolution, this way of constructing law-like sentences through the PNS is mainly relevant to the Process of evolution, whereas the Pattern is most likely to show nonexplanatory regularities.

So, if evolutionary theory is not, as Smart contended, a nomothetic science, neither is it a class of empirical generalizations combined with some mathematical tools. Moreover, in addition to the PNS, there is surely a set of genuine laws in evolutionary theory, since its core, population genetics, provides some models, such as the Hardy–Weinberg equilibrium, which prescribes a nomological necessity to any pool of genes in an infinite population. However, those kinds of propositions are not so much empirical laws as \textit{mathematical laws}. They define a sort of mathematics of genes. Such models are in no case a description of any actual population, for in order to be applied to populations they have to integrate empirical content, i.e., by fixing the fitness coefficients of alleles. But this is not the same thing as fixing the parameters (mass, charge, etc.) in any standard

\textsuperscript{9} By changing the definition of what counts as law, and, more precisely, weakening the DN requisites on laws of nature, one can imagine that there is a continuum of kinds of laws instead of a sharp boundary between accidental and nomological generalization. For example, relying on the supporting counterfactual requisite, Woodward (2001) defines laws as statements invariant through a sort of change in the explanandum. This enables him to count several laws, like Mendel’s laws, in biology, and then account for the predictive and explanatory role of an accidentally general statement such as the universality of the genetic code. My point is that characterizing the status of the principle of natural selection within such a continuum is still at stake.

\textsuperscript{10} A similar position is upheld in Brandon (1996) and Michod (1981).
physical case, because fitness can only be \textit{locally} defined, its relevant parameters being determined by the environment considered.\footnote{For example, color of moths is a fitness parameter in industrial melanism only because there are predators capable of vision.} And, even worse, those parameters are likely to change without change of environment since many cases of selection are frequency dependent. Admittedly, over three decades, after Maynard-Smith (1982), we have developed a powerful mathematical tool to build models in cases in which selection is frequency dependent, e.g., the value of a trait in an individual depends on what other individuals are and do: this is \textit{evolutionary game theory}, which can provide models in which ordinary population genetics fails because it treats fitness as a property of individuals and hence cannot forge models when fitness depends on frequency. The status of those models, however, is the same as that of the classical models of population genetics. Maynard-Smith (1982) insisted on the fact that one has to investigate the \textit{strategy set} before applying any game theoretical model to empirical cases, which means that by itself, game theoretical theorems and proofs, no matter how illuminating, do not have empirical content. So, in a way, evolution contains both statements stronger than physical laws (since they are purely mathematical models) and statements nomothetically weaker such as those derived from the PNS by its empirical instantiation. Rather than a law, the PNS in the end proves to be an \textit{explanatory schema}, providing ways of explaining and building models through its more or less empirical instantiations. The least empirically instantiated are models of population genetics; at the most empirically instantiated level, we have law-like generalizations, such as paleontological ones. In a way, it is a matter of convention whether or not to call them “laws”: the point is just to determine their epistemological nature.

\subsection*{2.2.1.3 Historical narratives and selective mechanisms}

As Bock and Von Wahlert (1963) wrote, one must distinguish the processes of evolution, which involve—but are not to be equated with—natural selection, and the outcome of evolution, namely phylogenies and the Tree of Life. However, no actual process of evolution could be understood solely through knowledge of mechanisms and without historical data. Let us give an example. Many terrestrial vertebrates are tetrapods. One could imagine a selective hypothesis concerning the adaptive origins of their four limbs since they are obviously adaptive for locomotion. However, there is another reason for those four limbs: marine ancestors of those vertebrates had four fins, so the four limbs are a legacy,
resulting from what we can call “phylogenetic inertia.” The point is that natural selection often explains the appearance of such traits but not in this precise clade, so the selectionist explanation has to be historically situated in order to determine what the correct explanandum is, for which natural selection would be the right explanans. Thus, no understanding of the presence of characters in the organisms of a given population or species is available through the sole application of models of natural selection. The specific character of evolutionary theory, if we consider that its explanatory strategies are always related to some use of the selectionist explanation, is that it brings together some formal models, written in mathematical language and in the modality of pure necessity, and some historical narratives, which allow scientists to instantiate the modes of natural selection in actual cases. Paleontology as well as the population genetics of given groups, species or clades, is essentially committed to a double-faceted scientific conceptuality, both historical and nomothetical.

The methodological aspect of this status is that no empirical inquiry in evolution can be made without comparative data, or some incorrect ahistorical use of natural selection mechanisms, such as the one exemplified previously, is always possible. And often the divergence of results between inquiries has to be traced back to differences between the sets of comparative data used by the researchers (Sober and Orzack 1994, 2001; Griffiths and Sterelny 1999 pp 240–250).

This pervasive character of historical narratives in neo-Darwinism accounts for the historical meaning of all biological terms throughout evolutionary theory. Taxonomies are obviously and easily reinterpreted by history, and the concept of homology that helps systematists to build their classification immediately acquires the historical status of “common descent’s sign” like bird’s wings and bat’s wings. Homoplasy, as the other kind of similarity across species, seems at first glance less historical: similar selective pressures gave rise to similar devices, as adaptations to such contexts. But is the concept of adaptation lacking any historical dimension?

The question of whether adaptation is a historical concept is widely debated. Even if it is admitted that “adaptation ascription are causal-historical statements” (Brandon 1996), since to say that a trait is an adaptation is to say that it has been somehow selected for some of the advantages it gave to its bearer via differential

---

12 On phylogenetic inertia, see Sober and Orzack (1994, 2001), Reeve and Sherman (2001), and below 2.2.2.

13 A case for historical narratives in evolutionary theory is made in Richards (1992); compare with the critique by Hull in the same volume. Gayon (1993) addressed the dual character of evolutionary theory.
reproduction, it remains to be decided whether this provides the whole meaning of the concept—given that, in fact, biologists often do not appeal to historical inquiries in order to describe adaptations but just forge optimality models with current data. Reeve and Sherman (1993, 2001) advanced a powerful “current concept” of adaptation, opposed to the historical concept sustained by the majority of philosophers of biology in accordance with Brandon (Sober 1984; Ruse 1986; Griffiths 1996). They propose that: “an adaptation is a phenotypic variant that results in the highest fitness among a specified set of variants in a given environment” (1993 p 9). Having distinguished two goals of evolutionary research, the first being the explanation of maintenance of traits and composition of population, and the other the reconstitution of history of lineages, they argue that the former essentially needs the current concept, while the latter is much more related to the historical concept. Notwithstanding one’s conclusion, the fact that there is a historical component of adaptation ascriptions is important, since it allows biologists to distinguish between the origin of a trait as an adaptation and its current presence and maintenance.14 A trait that is adaptive might not have emerged as an adaptation or might have emerged as an adaptation for some other use: this is grasped by the concept of “exaptation” suggested by Gould and Vrba (1982), an example of this being the insect wings that probably emerged as thermoregulatory devices (Kingsolver and Koehl 1989). Exaptation has proved to be a useful concept for understanding a lot of features that appeared during the evolution of hominids (Tattersall 1998).

However, one should not conflate two meanings of the historical characterization of adaptation: there is a definitional meaning and an explanatory meaning. On the one hand, selection defines adaptation, since a trait being an adaptation means that it originated through natural selection. But on the other hand, we say that selection explains adaptation: is not this contradictory to this definitional meaning? Not at all, because by this we now mean that the explanation of a given adaptation may search for concrete selective pressures in the given environment, and this provides an agenda for experimental testing of hypotheses. An example of such experiments, and then of the explanatory use of the historical concept of adaptation, is the study by Antonovics of the differential sensibility of plants to gradients of metal in soils (Antonovics and Turner 1971).

14 Sober (1984), followed by some writers, calls it “adaptedness” in order to distinguish it from “adaptation”.
2.2.1.4 A formal characterization of selectionist explanation and the issue of units of selection

The precise characterization of adaptation has been the focus of a large controversy in biology, and the philosophy of biology, about what exactly is likely to be adapted. Wynne-Edwards (1962) claimed that groups and populations were sometimes adapted. This meant that natural selection worked in favor of groups or populations, which sounds contradictory to the fact that individuals are the entities subsisting and spreading through selection. Williams (1966) gave a forceful defense of selection and hence adaptation as bearing exclusively on individuals. And, since the determinants of hereditary variations that are selected are genes, he concluded that selection acts primarily at the level of the genes. It is to be remarked, however, that he did not refute the logical possibility of adapted groups and then group selection, but proved that the alleged cases of group selection were explainable by natural selection at the level of genes, which is somehow more theoretically parsimonious.15 Along those lines, Dawkins (1976, 1982) elaborated his view of genic selectionism (or the “gene’s eye view” of evolution), trying to account for all manifestations of selection.16 One must here distinguish genic selectionism, which is an assertion about processes of selection and selectionist explanation, from genic determinism, which means that all phenotypic traits are wholly caused by genes with no impinging of environment or learning. One could perfectly subscribe to genic selectionism without genic determinism, as did Dawkins himself, and Dennett (1995) or Rosenberg (1985). Some practitioners or propagandists of sociobiology did make this confusion, which bore some hazardous moral and political consequences that in turn proved quite damaging for serious research conducted in those fields. But the genic selectionist’s concept of gene only requires that the presence of a gene in a genotype in an environment makes a difference relative to the lack of this gene in the same context; the weaker requisite is that genes be “difference makers” (Sterelny and Kitcher 1988), and here there is no commitment to any assumption about what genes determine and through which channels. This idea is the meaning of the locution “gene for” which unhappily has been read in a deterministic sense. Genic selectionism does not prevent an environment from being as much a determinant as genes in the success of a trait (Gray 2001).

15 In fact, Williams (1992) elaborated and defended the concept of clade selection, added to gene selection.
16 On the differences between Williams’ conception and Dawkins’ gene’s eye view, see Kenneth Waters (1991).
One of Dawkins’ major arguments was the concept of inclusive fitness developed by Hamilton through his research on kin selection. Here, turning to the level of genes within selective explanation appeared fruitful in studying such features as cooperation or altruism that sounded at first glance contradictory to natural selection as enhancing the individual’s fitness. The question, then, was to determine a level at which natural selection could explain the fact of altruism such as sterility of males in some hymenoptera species. Altruism has been selected because, although it decreases the fitness of the altruistic individual, it increases the representation of its genes in the next generation, provided that the individual is closely enough related genetically to individuals benefiting from this altruism. This is the case in insect societies that are essentially kin societies.

Genic selectionism has been challenged in several ways by Gould, Lewontin, Sober, and Brandon. One main argument is that selection acts only on phenotypes hence is blind to genotypes. Therefore, the level of genes is not relevant for understanding selection. Many genotypes, hence many genes, are identical selectively provided that they are “genes for” the same phenotypic trait. Using a notion elaborated by Reichenbach and Salmon in a philosophical debate about probabilities, the argument states that phenotypic interactions screen off the efficiency of genotypes and their relationships with environment. It does not deny that together with environments genotypes cause the phenotypes, but rather that this kind of causation does not explain the outcome of selection since it is necessary and sufficient for this purpose to consider the effects of the interaction of phenotype with its biotic and abiotic environments.17

The other line of defense, stated by Lewontin and Sober (1981), is the context-sensitivity principle, which claims that, since the phenotypic effects of a gene depend on the environmental and genetical context of its expression, a single allele cannot be the bearer of the selective causal process. The authors’ example is then the case of heterozygote superiority, since in this case the diploid genotype (e.g., AA, or Aa or aa) and not the single allele (e.g., A or a), is the genuine entity supporting the selection process. One can surely mathematically describe what happens to the single allele, but this gene’s eye view account is not causally explanatory.

Although biological evolution has been theoretically defined as a change in gene frequencies, the fact that the general model of the process of selection is not committed to any determination of the entities undergoing natural selection

17 A screens off B as a cause of C iff Pr (C/A&B) = Pr (C/A) ≠ Pr (C/B). Sober (1992) contested that “screening off” can yield a rebuttal of genic selectionism, since the argument is open to an almost infinite regress within which sometimes the most important explanatory cause is not the one which screens off all others.
implies that they are not necessarily “genes.” Hull gave a formulation in terms of replicators (hereditarily reproducing entities) and interactors (entities whose causal relationships affected the hereditary success of the replicators they are associated with). In most classical cases of natural selection, replicators are genes and interactors organisms. The gene’s eye view, then, says that since genes are the replicators, they are the units of selection. But of course this formal definition could be applied to other cases, in which replicators could be species or clades, or interactors could be genes themselves or groups. A more fine-grained approach of the various processes of selection is, thus, allowed by this formal characterization. For example, in the case of meiotic drive or segregation distorters—cases important to Dawkins’ argument—genes are themselves the interactors. But the “replication” idea faces some specific problems since it mixes the idea of reproducing, and the idea of copying (Godfrey-Smith 2000a). Only genes replicate since organisms reproduce but they do not copy themselves; yet, unlike organisms, genes are not alone in the replication process, they are involved in a whole machinery (ribosomes, enzymes, proteins, etc.). However, this machinery allows the differential expression of genes in the genome through regulation of their transcription into mRNA and proteins. This transcription might be thought of as a copying of the gene, but it is not really a reproduction, since it is a process distinct from the replication of the cell in mitosis or inheritance through meiosis. Moreover, this copying process is submitted to the regulation of gene expression, contrary to the replication in mitosis. The general conclusion is that in no case are “copy” and “reproduce” synonymic or correlative notions, which weakens the very notion of “replication.”

One point of interest of such a formulation is nevertheless that it can handle selection even outside biology, for instance, when we talk about cultural entities. The theoretical problem that faces this vision is to define a form of heredity in order to pick out the replicators. Hull thought that his formal characterization of selection was quite a logical one and embraced all possible cases. Giving the counterfactual example of the “protein world” that has no replication of entities, Godfrey-Smith (2000a) showed that the interactor–replicator couple is not necessary to the selection process as such; however, in our world, almost any selective process does rely on these elements.

---

18 Dawkins coined “replicators” but opposed it to “vehicles”; this word is too bound to the intuitive organism-genes difference.
19 For a general abstract account of theories using the concept of selection, such as immunology or evolutionary theory (“selection type theories”), see Darden and Cain (1988). For a theory of selection forged to address both evolution, immunology, and operant behavior, see Hull et al. (2001).
Easily expressible in this context, another argument against genic selectionism rests on the “parity thesis” (Sterelny, Griffiths), stating that all elements of the replication process are on a par (Griffiths and Gray 1994; Griffiths and Knight 1998; Oyama 2000), since environments as well as cytoplasmic elements or learned traits are “difference-makers” in the phenotypic outcome, exactly like genes. This thesis challenges both genic selectionism and genic determinism. Moreover, proponents of this theoretical alternative sometimes called Developmental System Theory contend that there exist kinds of heredity other than genetic inheritance, for example, nest styles, bird songs, or methylation patterns (Gray 2001; Jablonka 2001; Neumann-Held 2001). This challenge to gene’s eye view, consisting in a multiplication of the replicators, is more radical than the other critiques because the whole concept of the selective process has to be transformed. However, while accepting several kinds of replicators, Maynard-Smith and Szathmary (1995) trace a line between “limited” and “unlimited” inheritance, the latter allowing a quite infinite range of creation and transmission of elements. Only genes—and language—provide such an inheritance, which accounts for the extreme diversity and creativity of biological and cultural evolution.

The thesis of genic selectionism has been undoubtedly stimulating in compelling people to clarify their concepts and presuppositions. In fact, reacting to Dawkins’ extreme positions, some biologists did conceive of cases and mechanisms of group selection that could escape Williams’ critique. Nunney (1999) tried to define lineage selection, an idea that was suggested by Hull (1980), whereas Gould invoked a species selection (for properties, such as size, sex, etc.) that Williams (1992) refuted, although admitting and defending a clade selection above the level of genic selection. D. S. Wilson and Sober provided theoretical grounds for the use of group selection (Sober 1988a; Wilson 1992; Sober and Wilson 1994, 1998), and, especially in Unto others, designed a pathway from evolutionary altruism to psychological altruism. Their argument first relies on

---

20 The gene’s eye view defense has been the notion of information, in order to qualify the specificity of the genes’ role against other factors. Information should be semantically defined. It is not a simple usual correlation (fire–smoke) that is always reversible. Maynard-Smith (2000) elaborated this option, but difficulties raised by Godfrey-Smith (2000b) are numerous and go against a univocal notion of biological information.

21 Clear formulations of the DST program are given by Gray (2001) and Oyama (Oyama, Gray, Griffith 2001). On the developmentalist challenge and its integration into evolutionary theories, see later.

22 Gray (2001) provides a critique of the distinction.

23 Williams’ argument is that only a set of gene pools can behave in the same way as a gene pool when it comes to natural selection. Hence, there is only clade selection above the level of gene selection.
distinguishing and comparing within-group and between-group selection processes. Wilson and Sober’s argument invokes a “common fate” (Sober 1988a) of individuals in a group selection process, which implies that the selection process is compelled to act on all those individuals as a whole; then, secondary selective processes maintain this common fate, and selection can act at the level of the group. One consequence is that even kin selection appears as a form of group selection, rather than being genic selection’s underpinning of an apparently altruistic phenomenon. Group selection, however, is not exclusive of genic selectionism, since its point is that groups are vehicles; it is yet another question to decide whether or not genes are the only replicators involved.

Concerning genic selectionism, two strong positions are opposed nowadays among philosophers of biology. The first one, formulated by Brandon (1988) is pluralism: it states that there are several levels of selection and several units of selection. It is then an empirical question to know in any given case which are the actual forms of natural selection, but most empirical evidence is in favor of selection above the level of organisms in some cases, added to selection at the level of genes. The opposing position is defended by Sterelny and Kitcher (1988), who claim that there is always a genic selectionism which operates together with any kind of selection, even if we cannot have empirical access to this level, and even if it is pragmatically more interesting for biologists to recognize supraorganismic selection processes and treat them as such. The genic level is always the “maximally informative” one.24

Those philosophical considerations do not, in fact, impinge on biological investigations. It seems that biologists are in practice mostly pluralist on this issue (for example, Williams 1992), but it is not clear whether the decision between the two contrasting positions could be settled by the results of empirical inquiry. Some biologists, in fact, ignore those considerations and take for granted, since it is required by their practice, that there are several levels of selection (Keller and Reeve 1999) that have to be studied for themselves. But the recognition of the plurality of levels—notwithstanding the question of its ultimate theoretical reducibility to a genic one—gave rise to the important biological issue of their articulation. Michod (1999) elaborated the schema of a Darwinian dynamics, which accounts for the progressive emergence of new kinds of units of fitness: macromolecules, genes, cells, organisms, etc. The process relies widely on trade-offs between decrease in fitness in lower levels (for example, association of

---

24 Lewontin and Godfrey-Smith (1993) showed that even if an allelic descriptive and predictive model is always possible in cases classically opposed to genic selectionism, provided that one in some case enriches the model with conditional probabilities of alleles, however, those formal questions of adequate models do not decide the point of what is the causally relevant level.
individuals creating a common interest, which hurts the interest of the individual) and increase in fitness at the higher level (for example, the level of the association itself), and this trade-off is exemplarily a case of multilevel selection. The recurrent problem is then to find models that show how, in each case, the prime for defection (e.g., breaking the association), which is available each time there is a “common good” (Leigh 1999), can be overcome through this multilevel selection.

Although developed at a rather conceptual level, and mostly by philosophers, such controversies bear important consequences for the general meaning of the theory of evolution. What is at stake with altruism is the possibility of extending selectionist explanations in order to understand phenomena in the human domain. If altruism is explainable either by kin selection theory, or by Trivers’ reciprocal altruism (1971), which holds for populations of nonrelated organisms and is now derived from Game theory, particularly from the results of the study of the Prisoners Dilemma by Axelrod, then the issue of levels and units of selection is at the same time the issue of the foundation of an evolutionary approach, not only of the emergence of man and human societies but also of the current human psyche and societies through a selectionist framework, a research program now called “evolutionary psychology” (see below 3.2). Of course, altruism as studied by biologists is not what vernacular language calls altruism. For example, some very “egoistic” fellow (in ordinary language) would be biologically altruistic if he also wanted to leave no offspring; in contrast, a mother who sacrificed an entire life to her children, even if the perfect model of “altruism”, would from a biological point of view be typically selfish since she is entirely devoted to entities, which share 50% of her genes.25 So, no matter what the conclusion of the units of selection debate, all the lessons that might be taken from evolutionary biology into psychology have to be checked regarding whether they use vernacular or technical concepts and whether they do or do not carry illegitimate confusions between those two meanings.

2.2.2 Limits of selectionist explanation

2.2.2.1 The debate on adaptationism

Even if selectionist explanation is capable of rendering intelligible many nonbiological facts, no matter how far this capacity will be proved to extend, there

---

remains the preliminary question of its limits within the field of evolutionary biology. Darwin said that the Tree of Life (first principle of Darwinism) was partly explained by natural selection (second principle), but that there were other mechanisms at work in its production. So, I now turn to the actual limits of selectionist explanation in explaining both the form of the Tree of Life and the peculiar features of organisms.

The question of the limits and conditions of selectionist explanation has been approached in what has been called the controversy about adaptationism. In a very influential paper, Gould and Lewontin described and criticized a too pervasive method in evolutionary biology, which they called “adaptationist program.” In short, adaptationism means to think that the majority of the most important features of the living realm are explainable by natural selection (Sober 1994a).

There have been many attempts to clarify this adaptationism (Sober 1994a; Amundson 2001; Godfrey-Smith 2001b; Lewens forthcoming) 25 years of spandrels. In the cited title, this program, in summary, consists of atomizing an organism into discrete traits, and then building a selective history which establishes how each trait appeared as an adaptation to solve a peculiar problem. The authors contend both that we cannot atomize an organism in any way we want and that each trait allows the reconstruction of a selective history which should be testable. Too often, biologists, be they ecologists, paleontologists, or ethologists, create “just so stories,” e.g., stories that invent a plausible scenario of the resolution of a supposed antique problem—the trouble being that there is no way to prove that such a problem existed.

I have no interest here in deciding the fate of adaptationism. In fact, the most salient consequence of the spandrels paper is the necessity of clarifying the implicit assumptions in the research on adaptations, leading to a real formulation of an adaptationist program, and forcing scientists to take sides on the question.

26 “I am convinced that natural selection has been the main but not exclusive means of modification.” (1859 p 6). First of all, sexual selection, that is here left aside. For its complex relationship with natural selection see Mayr (1965a) and then the current research on the evolution of sex (Williams 1975; Maynard-Smith 1978).

primarily through the questions of its limits within biology. And here the major
concept pointed out by Gould and Lewontin is “constraint.” By this word, people
mean various things and state of affairs, so some clarifications are needed.28
Constraints can be physical, such as the size of the genome, which entails some
impossibilities for rapid metabolism within a cell in salamanders (Wake 1991); or,
more obviously, an elephant cannot have thin feet. They can be of genetical order,
for instance, when two genes are too close to be separated by crossing over during
meiosis. They can be phylogenetic, meaning that selection acts on entities that
come from a determinate history and have then inherited features difficult to
change. For example, selection cannot adapt a respiratory system of vertebrates
by creating a perfect respiratory device but has to modify the preexisting devices
in fishes. A constraint is recognized by comparison across several species or
clades: the fact that giraffes, like all mammals, have seven neck vertebrae like
mice, indicates that the number of such vertebrae is a constraint, since we would
expect number of vertebrae to be more proportioned to size (therefore more
adapted). Moreover, phenotypes undergo genetic constraints, since there are
epistasies and pleiotropies which entail that a trait will, in any case, be accom-
panied by another trait which has no adaptive relationship to it. Or constraints
can be “developmental”—this word needs some further comment. Those mean-
ings, unfortunately, are not easy to distinguish in fact. But let us keep in mind that
this issue of the limits to the power of natural selection (of a given trait) facing
constraints is tightly bound to the other issue raised by Gould and Lewontin,
namely the impossibility of atomizing living beings into discrete traits. The set of
constraints in the end gives the conditions for a kind of form untouched by
selection but always slightly altered and reshaped by it, which after the German
morphologists Gould and Lewontin named Bauplan.

However, the emphasis on constraint should be best understood with refer-
ce to the recent evolutionary theory of development.29 Selection acts on
variants, but not all variants are able to develop from a given gene pool. The
evolutionary theory of development unveils the constraints on the rise of those
variants upon which selection is about to act. For example, Wake (1991 pp 547–
549) showed that in all species of plethodontidae, the feet have got four toes
instead of five in the ancestor from which they derived by miniaturization. This
happened in unrelated lineages, as an alternative state of developmental mechan-
isms sharply distinguished with the five-toes producing state. Adaptive processes

text.
select for size, and developmental constraints switch from five to four toes, independently of the lineage.

This example has nonetheless been challenged by Reeve and Sherman (1993) in one of the most convincing defenses of the adaptationist program. Their argument is rather simple: one can always appeal to selection even in Wake’s case, since it is possible that there is a selection at an embryonic stage that eliminates variants that have more than four toes. So, the case for developmental constraints is not so easy to defend in the face of elaborated and differentiated concepts of natural selection.

Wimsatt elaborated the helpful concept of generative entrenchment, meaning that, no matter whether or not selection acts on some feature, the fact that it has been built into the developmental program of a species at a rather early stage implies that it is easier, less costly, and more probable for selection to modify traits that appear later in development. Since to modify a very entrenched trait entails modification of numerous connected traits that are built on it, this modification is very likely to be nonadaptive, hence disregarded by selection. The more relative to the early formation of the organizational plan of a species a trait is, the more entrenched it is, so the less probable it is that selection will act upon it and modify it, hence it can be considered as a constraint for selection.

Clarification of this debate has been provided by Amundson (1994, 2001), by arguing that in the end, developmentalists and selectionists do not ask the same question. Selection is appealed to in order to explain why such and such variants arose and spread in the gene pool among a given set of variants; but developmentalists, on the other hand, try to answer the question of the nature of this set of variants: why are there these variants and no other variants, and to what extent is the emergence of some variants unlikely or impossible? This, in fact, is not exactly a constraint on selection because selection is an explanans to a different explanandum than the one developmentalists are interested in.

This recognition of pluralism within the various explanatory strategies in evolutionary biology is likely to eliminate the false problems created by the adaptationist debates and leaves philosophers and biologists with the task of formulating and evaluating what could count as an adaptationist research program. Following Godfrey-Smith (2001b) and Lewens (in press), it is useful to define two large categories of adaptationists, the empirical one, who makes assertions on the pattern of the Tree of Life and the actual mechanisms of evolution, and the methodological variety of adaptationism, who contends that

30 Wimsatt and Schank (1988).
31 Reservations are made about the generality of entrenchment by Raff (1996); a general critique of the concept is to be found in Sterelny (2000 p 377).
biologists have to suppose, first, the presence of adaptations, even if they recognize later that in fact the predefined adaptational optima are not reached and that constraints exist.

However, notwithstanding conclusions about the compared values of the many adaptationist programs or hypotheses, there is a larger fundamental issue to be addressed as a background to this question, namely the conditions under which we are likely to recognize the effects of selection and its place in relation to the other causes of evolution. I will first address the question of phylogenetic inertia related to selectionist explanation, and then I will turn to the question of the status of genetic drift.

### 2.2.2.2 Selection, drift, and phylogenetic inertia

Any model of real phenomena has to state a null hypothesis, namely, the description of a state in which there is nothing to explain, compared to which the actual state will have to be explained. Many radical changes in scientific thought, be they called “revolutions” in the Kuhnian sense, or more modestly “shifts,” consist in new definitions of the null hypothesis. For instance, Galilean physics began by conceiving of the rectilinear uniform motion as the “null hypothesis” (instead of rest), pointing out acceleration or trajectory changes as the right explanandum. And such a definition of the null hypothesis has been called “the principle of inertia.”

So, the words themselves suggest that phylogenetic inertia is the null hypothesis in evolutionary theory. In any population, traits have to be explained if they are not obviously the result of descent, e.g., if they are not homologous of traits in the ancestor species. Of course, the determination of the traits as homologous or not depends on the set of species that are to be compared. Thus, the preliminary definition of this set of compared species in order to account for traits in a given species is an absolute condition for applying the PNS. Wrongly determining homologous traits by inadequate specification of the initial set of related species to which the explanandum species has to be compared immediately entails false results (Sober and Orzack 2001). The “just so stories” stigmatized by Gould and Lewontin as unfalsifiable and abusive applications of the PNS often stem in the absence of data from such misunderstanding of the right null hypothesis.

However, methodologically, for a set of species, the relationship of homology and homoplasy implied by the statement of a null hypothesis is epistemologically related to the more fundamental principle of parsimony.\(^{32}\) It can easily be seen that

---

\(^{32}\) See this volume Chapter 5 by Folinsbee KE, Evans DC, Fröbisch J, Tsuji LA and Brooks DR. For a general philosophical account see Sober (1981, 1988b).
the more we judge there to be homologies, the less evolutionary lineages we have to draw on: this is a kind of parsimony, so Hennig’s auxiliary hypothesis can be called upon if one subscribes to epistemological parsimony. But the stronger, ontological claim of parsimony also supposes this way of defining the null hypothesis.

Phylogenetic inertia, however, is not incompatible with selection. We have to distinguish between the question of the origin of traits and their presence. When the traits exist by phylogenetic inheritance but decrease in fitness in the new environment and the new species, selection is likely to suppress them or render them vestigial. In the reptilian family, this was probably so in the case of the four legs when it came to the snakes. So origin and presence are two distinct topics. If the inherited traits are still present, one is allowed to postulate no negative selection, but a positive fitness value may promote stabilizing selection to keep them. So selection and inertia are not two competing hypotheses but are sometimes distinct explanans for distinct explananda, and sometimes complementary explanatory resources. In this regard, the idea of a null hypothesis in the question of the maintenance of traits has even been challenged (Reeve and Sherman 2001).

As early as the 1930s, Wright forcefully emphasized the evolutionary role of random processes (Wright 1932) such as genetic drift. The smaller a population is, the more powerful those kinds of processes are. This is a rather simple idea, since the same phenomenon is illustrated by the toss of a coin: a small sample is more likely to show a random bias (for example, seven heads versus three tails), than a large sample, which will show a half/half distribution of tails/heads, according to the law of large numbers in probability theory. So, in small populations, some genes, whose fitness is either equal or lower than other alleles, can go to fixation.

However, the concept of drift is not only a negative one, if it is connected with Wright’s other concept, the adaptive landscapes. The fact is that in a gene pool some combinations are local optima, and if a genotype is on the slope of this kind of local optimum, selection will lead it toward this peak. But there may be a fitness valley which separates it from another, higher, fitness peak so that its fitness will have to decrease in order to get it onto the other fitness peak. For this reason, only random drift, provided that population is small, can lead it through decreasing its fitness across the fitness valley toward another hill so that selection can, after that, lead it toward the global fitness peak. Then, through migration, the new genotype can spread. In this model, drift helps to increase fitness by moving genotypes to global fitness peaks. Drift is, then, together with natural

33 For the several interpretations of the adaptive landscapes see Gilchrist and Kingsolver (2001).
selection, the other process accounting for the evolution of species, modeled by the travel of genotypes across fitness valleys and hill climbing. Wright named this schema the “shifting balance theory,” and empirical evidence for its generality is sometimes given but is not generally persuasive.34

Of course, this goes against Fisher’s formulation that average fitness is always increasing; but the conditions of the two assumptions are not the same, since Fisher’s theorem speaks about large, theoretically infinite, populations. Hence, evaluating the conflict between Wright’s view of the role of random drift and Fisher’s claim of an overall selectionist view, according to which the fittest always invades the gene pool, entails a decision on whether large or small effective populations are mostly to be found in nature.

But random drift raises some epistemological questions (and a more metaphysical one that I will address in the next section). The issue is stating the difference between drift and selection: are they two competing hypotheses? A first model, explored in detail in Sober (1984), takes drift and selection as two kinds of forces acting on an equilibrium model formulated by the Hardy–Weinberg law (together with the forces of mutation and migration, which I do not consider here). If equilibrium is changed, then selection is acting; when the fitter allele is not fixed, then random drift must have perturbed selection. Outcomes are the result of the addition of selection and drift in an analogous manner to summation of forces in Newtonian mechanics. However, this model has been challenged in two papers by Walsh, Ariew, Lewens, and Matthen (2003, 2002). They argue that selection and drift are not equivalent forces since they are not as comparable as two directional forces in dynamics. They do not compete at the same level, because “natural selection” is not exactly a force like the sum of selection pressures, but a sampling effect, supervenient on the real selective forces (fight, predators, mate choice, foraging, reproduction...) in the same way that entropy supervenes on microphysical states of molecules. On the other hand, drift is another kind of sampling, in the manner of a sampling error (compared to the fitness coefficients). Since summation of forces presupposes that their effects are additive, therefore, are acting at the same level, one cannot logically treat the state of a gene pool as the composed effect of selection and drift; and, finally, to talk of forces proves in general to be misleading, even for selection.

The question is not an empirical one but concerns the logical types of those population-level theoretical entities or processes that are selection and drift. Epistemologically, this means that there may be such a gap between drift and selection that the model of composition of forces has to be replaced by a

34 Coyne et al. (1997).
thermodynamical model of macroscopic effects of the statistical accumulation of heterogeneous microphenomena. The analogy of selection is no longer gravity but entropy, and we know that entropy as a variable bears no causal effect. Whether or not Walsh, Ariew, Lewens and Matthen’s challenge is right, the point is that considering drift leads to no obvious model of selectionist explanation, since when one is about to derive empirical content from mathematical models of population genetics and the PNS, one has no sure principles for conferring an epistemological status to the process of selection. This does not affect our study of phylogenies or our making and evaluating models for its mechanisms, but the interpretations of those models, hence of the very nature of the mechanisms, are certainly at stake. If drift and selection are not to be compared as two different forces like electromagnetism and gravity in physics, Darwin’s statement about the composed nature of the processes of evolution, and the subsequent agenda of weighting the components, has to be qualified.

2.2.2.3 The scope of natural selection

Evolutionary theory puts together the Tree of Life claim, and the Selection principle; however, these two statements are not logically connected. We can imagine a possible world where there is selection and not one Tree of Life; Lamarckism gives a picture of the opposite possible world. The question then is the relationship between the two claims: to what extent is the Tree of Life accountable for by natural selection? This question was present but quite attenuated in Darwin since he thought of other mechanisms than selection (e.g., Lamarckian inheritance). However, it becomes urgent in the Modern Synthesis because it focuses on selectionist explanation in the forms and conditions outlined previously.

All the puzzles investigated in the preceding section concern the selectionist explanation in general, whether it is applied to speciation in a population and on a short time scale, or to what Mayr called “emergence of evolutionary novelties” (1959a) (such as the transition of the protostomes to deuterostomes). However, there is a difference between those two objects, and this raises another question about the scope of the selectionist explanations under consideration up to now. For instance, it is plausible that Wright’s SBT accounts for a lot of speciations on small time–space scales but that evaluating its validity on a wider scale may appeal to other criteria. Paleontologists distinguished after Goldschmidt (1940) micro- and macroevolution and wondered whether the same processes should be held responsible for the events in those two cases. Simpson (1944) argued that, even if macroevolution shows very different rhythms in different lineages, however, it
implies the same processes as microevolution. The main objection, from a paleontological perspective, namely the lacuna in the fossil records on a large timescale, could be explained by purely geological reasons with no need to postulate special processes to account for them. But Simpson felt compelled to isolate a “mega evolution”—e.g., emergence of new lineages—that cannot so easily be interpreted along the lines of microevolution. Of course, Eldredge and Gould were the most convincing proponents of the difference between macro and microevolution, with the paleontological theory of punctuated equilibria. This theory is, first of all, a reading of the fossil records which claims that discontinuity is not a result of geological lacunae (as Darwin tried to establish in the Chapter IX of the Origin) when they show no major transformation for a very long period of time followed by sudden change. Here, the process accounting for this record is interpreted as a dual one, composed of fine tuning adaptation, which is a kind of stasis, and then a quick general transformation of the body plan giving rise to a new phylum. If the first process is explainable by selectionist explanations, such as the one I have considered up to this point, the second stage needs at least a change in the conditions under which natural selection can operate—if we still assume that no other process is needed.

No doubt challenges to Darwinian gradualism were numerous before Eldredge and Gould: before the Synthesis there were saltationists like De Vries and afterward came the “hopeful monsters” proposed by the geneticist Goldschmidt (1940). As a result of this, Mayr (1965b) established that gradualism—meaning that no evolutionary change is due to a big mutation—is compatible with evolutionary novelties since any change (like exaptations of insect wings) or intensification (as in the evolution of eyes in some lineages) of function can account for many structural novelties. Punctuated equilibria is a really challenging theory because the difference in the form of the Tree of Life cries out for a difference in the nature or the conditions of processes. If we subscribe to the idea of Baupläne as an integrated set of constraints, as advanced by Gould and Lewontin (1978), then we might think that phases of stasis represent fine adaptive tuning of the existing Baupläne, whereas quick transformations represent the appearance of new Baupläne.

Nevertheless, this view rests on some orthodox considerations of selection: among the founders of the synthesis, Mayr (1965b) emphasized the stabilizing role of selection, which, given a particular environment, largely eliminates big mutations since, given the high degree of integration of most organisms they are probably deleterious and often likely to threaten functional integrity. Periods of stagnation are, therefore, to be expected, by the nature of selection. The crucial point, however, is the logical relation between large-scale and small-scale evolution. Founders of the synthesis, like Fisher and Wright, focused on
microevolution. However, some assumptions defining such evolution become false when we jump to macroevolution: environments are no longer stable, and they can change quickly and intensively; and phenotypic variation available is not stable either since a very different range of variation will be available if the time scale is larger.

This second parameter is connected to Gould’s other main concern, namely evolutionary theories of development, and the focus on heterochronies crucial to his *Ontogeny and phylogeny*. The question is: what are the constraints on the range of variation, and what constraints are about to change? Developmental constraints are likely to account for the restriction of available variation and then for the focusing of selection process upon fine adaptive tuning and finally for the puzzling outcome of stagnation in the evolutionary tree. If we want to understand the transformation phase, we have to turn to the modification of available variation and then to a possible change in constraints. To this extent, if a modification happens in developmental mechanisms, then we could expect an enlargement of phenotypic variation, a new field for selection and thus new evolutionary possibilities. This is because, if we consider that the features yielding this enlargement are deeply entrenched, we can understand that in this case selection will act upon many connected traits at many levels of the developmental process, and so a radical change of existing body plan is likely to result. This was Gould’s (1977) point, following De Beer (1958) concerning heterochronies: a change in the timing of development, involving many subsequent and connected transformations in the life cycle is more likely to transform the body plan of a species than is change in an adult trait. This sets the agenda for other kinds of evolutionary research, including not only the taxonomy of different mechanisms able to affect development and thus yield evolutionary novelties, but also an attempt of causal accounting for them (an agenda which is a part of the Evo-Devo program). The important discovery of *Hox* genes developed in Lewin’s studies on *bithorax* gene (1978; see Gehring (1998) for a historical account), which are homologous in arthropods and chordates, supports this thesis, since a slight replacement of such a developmental gene by the *Antennapedia* gene can give rise to a leg instead of an antenna in *Drosophila*. Setting aside the complexity of the cascades of interactions, the general idea is that great transformations of a Bauplan may be generated by slight modifications of some kinds of genes or of

35 Like in Gould (1977): heterochrony, paedomorphosis, neoteny are defined and exemplified.
36 Even if genes of this sort, such as Bithorax have been known since about 1915, a major stage in the emergence of Evo-Devo has been the molecular characterization of those genes in the 1980s, mostly by Gehring (see Gehring 1998). This revealed that homeobox genes are homologous across several phyla.
their expression channels (Arthur 1997) because the development and life cycles are affected at many levels. Whether this view will prove correct or will need a radical revision, such as DST claims, and no matter the range of biological cases to which they apply, its epistemological significance requires integrating developmental biology and evolutionary biology in order to assess the multiplicity of the processes needed to account for the varied features of the evolutionary tree.37

On large time scales, environments are very likely to change, not only due to the evolution of organisms and populations, but also because of general geological and meteorological shifts. This second dimension of mega evolution converges with the first one to present the philosopher (a) with an epistemological issue. It also inspired Gould in his stronger challenge to overall selectionism (b).

a. The epistemological issue is the following: when variation range and environment change, populations exhibit a response to selection constituted along parameters that were not previously relevant. It could be said, then, that populations and organisms are evolvable. But some features make them more evolvable than others. Hence, at this large evolutionary scale the question may no longer be the evolution of adaptations (with all the epistemological problems addressed previously concerning nature and limits of selectionist explanation) but rather the evolution of evolvability itself. Changing explananda, then, could shift interest toward other levels of selection than genes and individuals, for example, clades and populations, since some population-level traits, such as sex or polymorphism makes them obviously more evolvable (Gould, Williams, Sterelny). But it can also raise new questions, such as the evolutionary origins of those features of traits that make them easily evolvable: how, for instance, are we to explain the cohesion of genes in a chromosome (Keller 1999), modularity (Wagner 1995; Sterelny 2004) or redundancy? So shifting the scale in the Tree also shifts interest from epistemological and methodological issues proper to selection, drift and inertia, to a general concern with new objects, such as modularity.

b. In Wonderful Life, Gould tried to trace the philosophical conclusions of the recent analysis of the Burgess shale, particularly by Withington and Conway Morris. His verdict was that many phyla appeared with the Cambrian, of which only few survived; thereafter, very few new body plans and phyla were really “invented” through evolution. But this creativity in evolutionary novelty is somewhat puzzling and raises a concern for the new explananda stressed previously. With the famous metaphor of the film of life rerun, Gould suggested that the history of life was much too full of contingent events, such as the mass extinction that killed more than half of the Burgess phyla (plausibly after the fall of an asteroid, according to the Alvarez hypothesis). The punctuated equilibria claim was a weak challenge to an overall view

---

37 Gilbert et al. (1996).
of selectionism since it can be reinterpreted as the necessity of defining two regimes of selection, the second one including the aforementioned concepts and concerns stemming from developmental theory. This latter view presents a strong challenge, since selection, and the adaptive capacities of individuals and species, cannot prepare them to face mass extinctions due to excessively strong changes of environment. Hence, the ones that survived did not owe their survival to their higher fitness, and the explanatory and predictive power of natural selection is very limited at this level of the history of life. *Anomalocaris*, for instance, seemed quite well fitted to its marine environment and was undoubtedly a strongly performing predator, surely no less well adapted than *Pikaia*, which seems to belong to the chordate phylum; it nevertheless disappeared. Thus, major events are contingent with regard to the parameters ordinarily involved in natural selection. This “contingency thesis” heavily restrains the scope of natural selection.

The fate of this challenge rests on a lot of empirical elements that are not yet available. In particular, the diagnosis of the Burgess fauna is still debated since Conway-Morris himself revised his original judgment (1998) and estimated that many Burgess phyla are in fact ancestors of already known lineages. However, as Gould pointed out in his reply (Gould and Conway-Morris 1999), the point is not whether or not there are other mechanisms than natural selection, a conundrum that we are unable to solve, but whether there were many more new phyla in the Cambrian, a great part of which effectively disappeared. The contingency thesis relies on an affirmative answer to this question, which should be studied by paleontological and morphological means. So notwithstanding the strong challenge to selectionism, the important consequences for the interpretation of the history of life rely on empirical investigations. But the question is likely to be begged by methodological considerations involving disparity. If diversity means the variety of species, disparity means the heterogeneity of the body plans. Gould contends that whereas diversity may have increased, disparity decreased. But even if we knew what the Cambrian phyla were, this would not entail the ability to measure disparity (Sterelny 1995, 2000). Cladists mostly think that we can trace the genealogy of phyla, but not evaluate the distance or difference between two phyla, because the criteria are always instrumental. In this view, Gould’s thesis would not be testable. The basic question, beyond the measure of disparity, is the

38 For example, *Hallucigenia*, once viewed as a quite unique species in its phyla, if turned upside down could enter into the phylum of the echinoderms (Conway-Morris 1998).

39 An argument against the contingency thesis would be convergence, if similar features appear several times in different lineages, they are more likely to appear even if we change some initial conditions of evolution (Sterelny 1995; Conway-Morris and Gould 1999). But such an argument makes use of excessively undefined notions of necessity and identity.
counting of body plans, hence the definition of body plans. Failing any consensus about that, the contingency thesis, whether or not empirically adequate, is not likely to be tested.

From a distance, the current state of evolutionary theory may in general be characterized as facing two kinds of challenges, weak and strong. Weak challenges imply, if successful, a revision of some part of the theory in order to integrate new methods and concepts; strong challenges entail giving up some major credos of the Modern Synthesis. In the case of Gould’s punctuated equilibria and contingency thesis, those two challenges focus on the first Darwinian claim, the form of the Tree of Life. Here, the strong challenge would lead us to give up both gradualism and the hope of finding a general account of the history of life through one explanatory schema.

But the same situation arises in the case of the second Darwinian claim, concerning the process in evolution. Here, challenges are forged by developmentalists. The weak challenge proposed by Evo-Devo involves a rethinking of the conditions and mechanisms of selection when it comes to development and the origin of evolvability. The strong challenge is formulated by DST proponents and entails giving up the concept of gene or its main role in inheritance and selection.40

2.2.2.4 Preliminary assumptions concerning the view of selection

The controversies addressed here over the limits and scope of natural selection, although not devoid of empirical content, are largely dependent on the conception that the authors have of the nature of selection. So far, I have left aside the most general alternative regarding this conception, an alternative which provides both a negative view and a positive view of selection. In the former option, selection merely selects, hence it just sorts high-fitness traits against low-fitness ones; in the latter option, selection is by itself creative. Mayr (1965b) claims selection is not a “purely negative force” since it gradually improves existing traits. Among biologists, this positive view is widely held: Dobzhansky, Simpson, and Gould shared Mayr’s view.

The general question underlying this split is: what does selection actually explain? It does not explain why this individual has this trait (this is due to

40 Kitcher (in Gray et al. 2001) and Sterelny (2000) are moderate appraisals of the extent to which the developmentalist challenge demands revision of the evolutionary theory. Kitcher (2004) is also sympathetic with Gould’s weak challenge but defends neo-Darwinism against Gould’s strong challenge.
developmental effects); as a population-level explanation, it explains precisely why this trait, once it had arisen, pervaded and persisted in a population. Thus, Sober (1984) subscribes to the negative view that selection is a population-level explanation, as we noted, so that the question “why is trait A in individual B?” does not belong to what it explains.\(^{41}\)

Neander (1995) challenged this view in a paper expressing the epistemological substance of Mayr's intuition. Apart from the two questions that I have distinguished (the “developmental question” and the “persistence question”), there is the “creative question,” which is: why did the genetic and developmental devices underpinning a given trait arise in a population? Contrary to the positive view, Neander contends that natural selection contributes an answer to this creative question. Perhaps speaking of creation is misleading because of the connotations of the word, evoking an instantaneous happening. I give here a slightly modified argument. In fact, even if the genotype conditioning the new trait is not created by selection, selection does increase the probability of the several genes composing this genotype, given that some of its genes have already arisen. The point is that, if a high fitness trait has a genotype \(G_1 \ldots G_9\) (measured in a model of the fitness of possible genotypes), and if \(G_1\) spreads into a population, then without hypothesis of selection at all, \(G_2 \ldots G_9\) are not more probable (than other alleles) than before; but under the hypothesis of selection, once \(G_1\) is there, the probabilities of \(G_2, \ldots G_9\) being fixed are significantly raised since they are part of the higher fitness genotype \(G_1 \ldots G_9\) and are more likely to appear than the less fit \(G_1G_2G_3 \ldots G_9\). So selection has \textit{causally contributed},\(^ {42}\) not only to the spreading of the genes \(G_1, G_2, \ldots G_9\) in the population, but also to the emergence of the integrated genotype \(G_1 \ldots G_9\), namely, the novel trait we are considering.

This defense of the positive view of selection can be extended. Natural selection is a three-stage process, variation, differential reproduction as effect of the variations, and change in gene frequency. But the two first stages are not easy to distinguish, since, although variation is conceived as resulting from mutation and mostly recombination, selection may affect the regime of variations, and therefore, controls the very parameters of its own exercise. It has been shown in some bacteria exposed to stress that selection can enforce the mutation

\(^{41}\) Of course, the issue of explanation is correlated to the question of causation: “what does selection actually cause?” More strongly committed than Sober to the Negative view, Walsh (2000) claims that natural selection is not even a cause of adaptations, since strictly speaking their causes have to be found in the developmental life cycles of the individual and forces acting upon it. Selection is merely a sorting process that presupposes such real causes.

\(^{42}\) At least in the probabilistic sense of causation, meaning that a cause increases the probability of its effect.
rate, providing an advantage in the range of available selective responses to environmental shifts.\textsuperscript{43} The notion that mutation rate is somehow controlled by selection, whereas mutations are the material upon which selection acts, demonstrates a kind of reflective impinging of natural selection on its own parameters. Such a reflexive structure of selection allows one to say that the traits selected are themselves dependent on the form of selection pressures, hence that they are somehow shaped, not only sorted, by selection. In the present case, even if the content of mutation is not given by selection and is prior to selection, any individual mutation is still counterfactually dependent on selection since the probability of its occurrence is directly dependent on the mutation rate. In the same spirit, Mayr (1970) suggested years ago that competition itself is under the control of selection (since too much competition could render selection impossible). To this extent, it seems difficult to separate positive causes of the new individual phenotypes emerging (“shaping”) from negative causes affecting their spreading or extinction (“sorting”). So, provided that the causal and explanatory regimes of natural selection are conceived as different from the explanatory regime at the individual developmental level, the positive view of selection is likely to be adopted.

2.2.3 Metaphysical issues about natural selection: some problems with realism

At many times, the issues exposed here involved a general metaphysical question, which is the problem of realism. Under this name philosophers of science try to understand the status of theoretical entities, such as electrons, oxygen, energy, gene, etc.—entities, which are often nonobservable. Roughly speaking, some defend realism, which means that those entities, and the process that involve them, are real things, whereas others are instrumentalists or pragmatists, which means that those terms gain there meaning only in the context of the scientific inquiry, mostly to allow predictions and other tests.

The fact that natural selection itself could not achieve the status of general physical laws alerts us that the problem of realism could be different in biology and physics. Rosenberg (1994) convincingly defended the thesis that evolutionary biology, as opposed to physics, must be conceived of instrumentally. One of his chief arguments is the supervenience of every concept bound to natural selection. Since natural selection selects for effects notwithstanding their causes (e.g., it

\textsuperscript{43} Andersson, Schlechta, Roth (1998); Mc Phee, Ambrose (1996); Taddei, Matic, Radman (1995).
selects for function no matter the physical structure realizing it), according to a natural-selectionist’s point of view different real processes and entities are treated as the same thing, which implies that this is an instrumental perspective since it abstracts from the differences between those infinitely varied real processes. “Instrumental” here means that natural selection is a concept so coarse-grained that it misses the fine-grained distinctions between real processes, albeit still useful for us in making the depictions we are interested in, since the fine-grained knowledge of all those processes and entities is out of our grasp.

The case for instrumentalism arises also in the context of another issue addressed previously, namely the units of selection controversy. Arguing against genic selectionists, some authors (Sober, Brandon, and Gould) accept that processes, even of group selection, can be described at a genic level since in the end evolution is change in gene frequencies—while contesting that this is the description of what actually happens. Thus, they suppose that the selection process is real and not dependent on our cognitive interests, and in this case the question is to specify the exact level of this process. Realism makes the controversy over units of selection more pressing. On the other hand, pure instrumentalism would dissolve it into the methodological question of the best mathematical model for a given process.

Realism in this context means that there is one real process of selection, and we have to decide what identifies this real process. Realism, of course, does not preclude any option regarding the debate itself: one can be a realist genic selectionist, allowing group selection to be an interesting description of phenomena, but one that does not identify the real process. But due to the structure of natural selection, it is not certain whether this sharp distinction between a real process and a convenient description holds. Following a suggestion by Kenneth Waters (1991), I will stress some consequences of the context-sensitivity principle.

Single genes, considered at a population level, are selected for or against with regard to their context, which means the environment of their phenotypic effects and principally their genetic environment (Mayr 1965b). Their selective advantages are context-sensitive. But the argument applies, finally, to any presumed unit of selection: its fitness depends on the whole interaction. Even Dawkins (1982) uses it in order to reject the claim that nucleotides in the end could be the real units of selection (their context is the entire allele).

But given that we are considering a population of such entities, contexts (environments for organisms, genetic environments for genes, etc.) are not always likely to be homogenous. Even in the classical case of Kettlewell’s industrial

---

44 This is still the line of Sober’s reply (1990) to Sterelny and Kitcher (1988).
melanism, there are places in the woods where trees are mostly white, others
where trees are mostly black, and in each of those contexts fitness values of black
moths and white moths differ. Then the fitness value of the entity is obtained
through averaging the various values across the varied homogenous contexts.
Now, if we are tough realists and claim that only causal interactions in nature,
such as the selection or deselection of an entity within its given context, are real,
those averaged values will be mere convenient placeholders for the real processes.
But in this case—and this is the most important point—the argument holds
equally against genic selectionism and against organism-level selectionism, since
as averaged, all fitness values are such placeholders. So if we do not want to
collapse into total instrumentalism, we have to accept that selection processes
with averaged fitnesses at many levels are different ways for us to describe the
same real process and the unique way to get real information about it. But at all
those levels, different forms of information are complementary.45 Picking out the
supposed real processes, each in its single context, is not exactly the job of the
evolutionary theorist, but he or she has many ways to describe the same multi-
plicity of processes. If there is in fact one real process, it nonetheless must be
addressed at several descriptive levels. Kenneth Waters calls this a “tempered
realism” because it tempers the sharp distinction between real theoretical entities
involved in single-context selective processes and instrumental concepts.

This case for pluralism has to be distinguished from the multilevel selection
advocated by Brandon or (in another way) by Sober and Wilson and from the
Sterelny–Kitcher theory. In Brandon’s pluralism, there are many possible forms of
selection, but there might be cases in which selection plays only at one level.
Pluralism is then compatible with tough realism. In contrast, pluralism sustained
by tempered realism contends that there are always several levels of description
for a same process—context-sensitivity implying that there is no way of discrimi-
nating what is the “real” process from descriptive reconstitutions of processes.
This last assertion contrasts with Sterelny and Kitcher pluralism since these
authors claim that the genic level description is “maximally informative,”
and—unlike other types of selection—is in all cases available. Tempered realist
pluralism is not committed to such a genic privilege.

The controversy about units of selection was not expected to be solved by
those considerations, which had two interests: to exemplify the fact that episte-
mological essential debates in evolutionary biology bear important metaphysical
consequences and to illustrate the requisite of forging a definition of realism
proper to evolutionary theory when we are about to discuss those metaphysical

45 According to Kenneth Waters (1991) each description is dependent on the prior decision on how
to discriminate between environment and selected units.
matters. In this perspective, the idea of tempered realism should contain lessons for other entangled debates about the metaphysical and epistemological sides of evolutionary biology. Due in particular to the epistemological status of natural selection, no general assertion from philosophy of science can decide the issue of realism within it and even enunciate what it would mean to be a “realist” in this context.

2.3 An evolutionary framework for philosophical issues?

A philosophical focus on evolutionary theory cannot ignore the huge consequences that Darwinism had for traditional philosophical problems, ranging from theological and moral matters to psychology. Since this field is as wide as philosophy itself, I will not even try a small survey but will instead indicate two or three perspectives on the fecundity and the difficulties involved in the use of evolutionary considerations in philosophical debates on human nature. Evolutionary theory pervades the whole theoretical discourse on man: from philosophy of mind and language to morals through epistemology.46 Two general motives can be distinguished: applying the power of selectionist schemes to problems outside biology; integrating traditional problems of meaning and culture within a large evolutionary framework, which permits asking anew the question of the origins of some devices (of ethics, of language, etc.), which has been avoided because of the untestability of hypotheses. In a strict sense, only the second strategy can be called a naturalistic evolutionary framework; however, the first one is almost always thought of within a naturalistic strategy.47 Here I will not consider issues in evolutionary ethics (see Chapter 25, Volume 3).

2.3.1 Selectionist models of culture and science

As we have seen, there exists a general formula of selection that does not specify the replicators and interactors. Thus, provided that we can establish heritability for some cultural or moral entity, a selectionist schema could render its birth and fate intelligible. Culture, and science or epistemology, are the most important

---

46 The main general philosophical account of the consequences of evolutionary theory outside biology is Dennett (1995).

47 “Naturalism” qualifies here any research program that formulates its questions and constitutes its method along the sole lines of natural science methodology, and that does not accept any entity originating and subsisting for itself above the nature studied by those sciences.
fields of explananda for those theories. It was noticed long ago that one human characteristic, whether unique or just developed to a unique extreme, is culture; and the fact is that besides genetic inheritance there is cultural heredity: individuals learn, and they can transmit what they have learnt, which appears somehow replicated. So, given that the transmitted items are likely to be slightly modified each time they are reproduced, a selectionist evolutionary account of culture can be worked out. It faces at least two big problems: the first one is the relationship between genetic and cultural inheritance. The fact is that an entity may have great “cultural” reproductive success while its bearer leaves no offspring. So there is no necessary genetic basis for cultural traits, although if a cultural trait enhances the fitness of its bearer—think of any medical device that fights illness—then this enhances its own reproductive success. The other problem is the definition of this “success,” given that cultural transmission is not only vertical as in heredity, but also horizontal (e.g., toward non off spring), and this dimension is at least as important as the vertical one for the spreading of a trait.

Boyd and Richerson (1985) formulated a powerful set of models for cultural evolution. They did not make general assumptions concerning the genetic bases of cultural traits, but clearly cultural evolution, with the vertical and horizontal dimensions of transmission, implicates rather complicated relationships with genetic evolution. One of the main results of the models is that cultural evolution is far faster than genetic evolution. This strengthens, justifies, and explains our intuition that since long ago in human history, biological evolution has been negligible compared to cultural changes.

There is a large methodological issue here: is this selectionist theory of culture analogous to natural selection in biology, or is it a part of this theory? Boyd and Richerson are quite neutral; Dawkins’s “memetic” sounds like an analogon of evolutionary theory. Other authors (Lumsden and Wilson 1981) are more committed to a “continuous” view, which includes a criticizable assertion on the genetic basis of cultural traits.48

The part of culture which is technique is susceptible to a similar evolutionary approach, and it may be easier since the problem of adaptation has many parallels with technical evolution (Basalla 1988). If we consider technique (for example, photographic cameras since their origin), it is even possible to draw an evolutionary tree similar to a branch of the Tree of Life, with extinctions, radiations, privileged lines of evolution, and so forth. And concerning mechanism, we have variation provided by changing fabrication technologies, and we have a kind of

---

48 A severe critique is to be found in Maynard-Smith (1996). A general evaluation of the possibilities offered to selectionist theories of culture in a quite sympathetic perspective is given by Kitcher (2003b).
process of selection since the more robust or efficient objects are more likely to be copied. Hence, it should be possible to define a property analogous to fitness. It is plausible that this field of the study of culture will be most likely to receive satisfactory evolutionary treatment.

Science is a limited area of culture subject to a specific constraint (namely, its aim to represent the world in some way). The foundationalist program for the philosophy of science, in quest for a priori rules and guarantee for scientific inquiry, declined in the 1960s following extensive critiques and philosophers after Quine turned to a naturalized epistemology, e.g., an epistemology situated at the same empirical level as the sciences, not considering them from an a priori point of view. In so far as they use selection, which presupposes no trend among the selected entities toward any end, evolutionary models of science have the advantage that they do not presuppose any shared rationality or ideal from the scientists and even no special competence to recognize what is true. It is a fact that no definitive formulation of the goal of science, of what is “objective truth” and the criteria to recognize it, has ever been enunciated; thus, we cannot presuppose that all actors are oriented toward the same goal. A selectionist process is able to produce theories with the tightest match to the real world, whenever theories bear any consequences in practical life (those consequences will be the effects upon which selection acts) (Ruse 1986). At the price of giving up the idea that science aims at eternal and ideal truth (Giere 2001), evolutionary epistemology with a strong selectionist commitment, as originally formulated by Campbell and variously advocated by Giere or Hull (1988), gives a clear picture of the “process of science” that conciliates the lack of empirically attested “aim” with the cumulative improvement of the fit between theories, data and applications.

However, the nature of replicators and interactors in this process is a confused issue: contents (and how to define them), scientists, etc.—although the clearest account of this perspective is Hull’s. So, one has to prove that truth of theories defines a kind of reproductive advantage, which is not obvious if the entities at issue are human beings. Giere’s verdict (1990) is that evolutionary epistemology is for the moment like Darwinism before the synthesis with genetics, hence it lacks a theory of the mechanisms providing heredity and variation

49 Evolutionary epistemology was not born with Campbell; in fact philosophers like Toulmin elaborated a so-called “evolutionary epistemology”. I consider only recent theories with their massive use of selectionist models.

50 Kenneth Waters (1990) provided a powerful critique of this Darwinian analogy concerning the growth of science, to the extent that it leaves apart intellectual powers of scientists as reflexive agents of selection of fittest contents.
across individuals. However, such an account might be now provided by cognitive sciences.

Like a selectionist theory of culture that is neutral regarding the biological foundations of cultural traits, evolutionary epistemology is not directly committed to any psychological theory of the acquisition of knowledge. There are some evolutionary theories, using selectionist models, that address this point, but this is “evolutionary epistemology” in another sense: “Evolutionary epistemology of mechanisms” (ETM) distinguished by Bradie (1984) from “Evolutionary epistemology of theories” (ETT) of science as a process. They could be complementary (as in Campbell’s Selection Theory (1990)), but they have no logical connection. In general, ETM can nevertheless be understood at an ontogenetical level, or at a phylogenetic level.

Now since this last ETM research program belongs to an evolutionary representation of mind within nature, in order to figure out the philosophical issues at stake, here I now turn to the other strategy, which builds a continuous evolutionary framework for solving questions concerning the nature of man.

2.3.2 Evolutionary psychology

When one talks about evolutionism in psychology, one nowadays could mean many programs, but here I will emphasize a very recent and influential one, namely evolutionary psychology.

The general framework of its strategy is the quest for adaptive value of the features of the human mind. Since the Tooby and Cosmides formulation, the guidelines of the program have been: the human mind is made up of separate cognitive modules that quite unconsciously effectuate successful determinate algorithms that have been constituted through natural selection as adaptations during one of the longest periods of hominization, namely the Pleistocene. One of the main hypotheses is the “cheater detection” module, supposed to solve the problem of discovering the free-riders in situations of reciprocal altruism—situations that should have been frequent in the Environment of Evolutionary Adaptation, and which have been analyzed in evolutionary game theory. Mating behavior and sexual dimorphism51 are an important subject of this research program, within which a robust explanation was provided of some social cognition modules (Cosmides and Tooby 1992), of our computationally amazing

---

51 Papers by Buss and Symons in Barkow et al. (1992), Sterelny and Fitness (2003). A powerful methodological and epistemological critique is given in Kitcher (2003b).
capacities to recognize faces, or of the origin of our ability to represent what others think (called “theory of mind”).\textsuperscript{52}

A large part of that research is conducted in linguistics because new theories of the origin of language become available when people question the adaptive significance of communicating through systems of signs (Pinker and Bloom 1992). Here, the evolutionary framework offers new possibilities in linguistics, among them Chomsky’s idea of a generative grammar embedded in innate competencies acquired through phylogensis, which was incapable of being worked out before one had such a framework.

The major assumptions in evolutionary psychology are that the mind is composed of “domain-specific” algorithms, in opposition to the most pervasive cognitivist hypothesis of some generalist algorithms that are embedded in our minds like some kinds of General Problem Solvers. Here, the psychological thesis fits nicely in the evolutionary framework, because if cognitive competences have been modeled as answers to particular environmental problems, they are necessarily domain-specific. Here, evolutionary theory allows authors to account for flaws or irrationalities in our mind highlighted by the work of Tversky and Kahnemann as a lack of adaptation of our cognitive abilities to our present times (since they were adapted in a very different environment) and also for our quite perfect ability to execute tasks generally unnoticed by traditional cognitivist psychology (recognition of faces, for instance). The last consequence is that cultural traits and institutions must be understood from a prior knowledge of psychological cognitive abilities (Cosmides and Tooby 1989).

Apart from the question of the genic basis of behavior and the commitment of some authors to rather dissatisfying views of genetics (Duprê 2003), evolutionary psychology faces several difficulties: the lack of informations concerning the original Pleistocene environment (which leads to the rise of just so stories),\textsuperscript{53} and the difficulty of testing the main empirical achievements of the research program since competing hypotheses are in circulation.\textsuperscript{54} More generally, the whole program is in need of clarification of what is to be counted as trait, since this decision effects all subsequent empirical investigations. Suppose that we are investigating the evolutionary significance of aggressive behavior: is it the “right”

\textsuperscript{52} Chisholm (2003).

\textsuperscript{53} Lewens (2004) gives a critique of the inference from a reconstituted Pleistocene problem to hypothetical cognitive module.

\textsuperscript{54} Two of the greatest achievements of the program—the Waist-To-Hip ratio theory in the field of mating strategies and the Wason selection task in the field of social cognition—are still severely challenged [Sperber and Girotto (2003) for the second one, with examples of equally corroborated rival theories; Gray et al. (2004) for both of them].
trait to explain? Or is it a part of a general disposition that responds either in a friendly way or aggressively to various situations? Or could it be a too general lumping of various traits: envy, jealousy, territorial ambition, etc.? (Sterelny 2000). Unless this conceptual problem is directly addressed, the whole evolutionary psychology agenda is likely to give birth to diverging, incompatible results with no way to discriminate between them and finally many underlying ideological motives to adopt one or another.

2.4 Conclusions

However interpreted, evolutionary theory is filled with theoretical problems concerning its major concepts (selection, fitness, adaptation) and hence its two major claims of the Tree of Life and of the Hypothesis of Selection. Those problems, albeit never empty of empirical and biological content, are at the same time philosophical since they involve conceptual matters that imply epistemological and metaphysical options. Although they cannot be solved independently of the biological results, and above all could not have been formulated without the acknowledged state of evolutionary biology, they are not likely to be solved only within biological science itself. But, reciprocally, their correct enunciation and the attempt at solutions are of vital interest to the fields of philosophy of science in general and of metaphysics.

However, the most tangible impinging of evolutionary theory on philosophy is the possibility that it gives to elaborate a new framework for many general problems and first of all about the nature of man. I have tried to show the interest of the research programs constituted in this direction, their variety, and the difficulties they are facing. No integrative and synthetic knowledge of man or methodological framework of philosophical problems has yet been accomplished in such an evolutionary spirit that would be parallel and compatible with (and in the end integrated in) the Modern Synthesis. For the moment, we have local results, new challenges never free of ideological and political commitments, and insightful ways of approaching long-standing puzzles (such as the origin of language, maternal attachment, or technological evolution). But in the end, it must be said that this will have profound consequences on the way we generally conceive of philosophical problems and most of all on the image of man that is concerned with those problems.55

Abstract

This chapter aims to review the relevance of ontogenic data in an evolutionary perspective. Phylogenetic investigation through developmental information is one of the most promising avenues to the elucidation of our natural history. First, the problematic integration of biological subdisciplines into the evo-devo synthesis is considered: the homeobox as Pandora’s box is discussed and the important role of a comparative morphology program is emphasized. Second, the study of development reveals essential aspects of primate supraordinal relationships and does not support an archontan reality. A special note defines the traditional superorder Archonta as (1) an artifact of the Scala naturae concept, since archontans were supreme public servants of the Greek ancient world. On the other hand, it is (2) a vehicle to explain the existence of flying mammals (Chiroptera) via a gliding intermediate stage (Dermoptera). Third, the impact of neotenic ideas on paleoanthropology is retraced and current contributions describing the evolution of the human cranial base and bipedalism are presented. Man’s domination by neoteny seems to be a burlesque, accurately related as pithecocentrism.
3.1 Introduction

The polymath Johann Wolfgang von Goethe was fascinated by the anatomical diversity of the animal kingdom and its variability of form. In 1817 (11 years before Karl Ernst von Baer published his embryological manifesto), he wrote:

- Man findet daher in dem Gange der Kunst, des Wissens und der Wissenschaft mehrere Versuche, eine Lehre zu gründen und auszubilden, welche wir die Morphologie nennen möchten [...] Er abstrahiert bei diesem Ausdruck von dem Beweglichen, er nimmt an, daß ein Zusammengehöriges festgestellt, abgeschlossen und in seinem Character fixiert sei. Betrachten wir aber alles Gestalten, besonders die organischen, so finden wir, daß nirgend ein Bestehendes, nirgend ein Ruhendes, ein Abgeschlossenes vorkommt, sondern daß alles vielmehr in einer steten Bewegung schwanke. ...¹

Life is obviously not a static arrangement but the particular result of a dynamic, ongoing process. This phenomenon is nowhere more relevant than for ontogenetic ongoing studies.

This review approaches some important aspects of ontogeny and phylogeny by presenting a selection of studies that exemplify this scientific field. Embryology, comparative anatomy, and especially molecular biology demonstrate an amazing unity among organisms, and sometimes bizarre variations among them stem from a series of basic themes, some of which are common to all living beings (Nielsen 1995). I concentrate here on broader matters, such as (1) comparative embryology, especially with regard to K.E. von Baer and its modern derivative: evolutionary developmental biology. The ancient realm of morphology plays a major role in this context. By the 1980s, molecular biology and paleoanthropology had developed their own concerns and controversies. Yet the significance of studies going beyond the analysis of adult phenotypes was already necessary and self-evident (Howell 2002).

Since hominin fossils, such as those from Dikika, Taung, Mojokerto, Nariokotome, Tešık-Taš, Kiik-Koba, or Le Moustier, represent infantile or juvenile stages, studying our phylogeny via ontogeny should be of particular importance, although, as Krovitz et al. (2003) pointed out, juvenile fossils are lacking for most species in the

¹ “It can be observed that in the course of art, knowledge, and science, several efforts are made to create and cultivate a doctrine that we may call morphology.... One abstracts the reality of fluctuation by supposing that a belonging together and a fixation of its character can be fulfilled. Considering all shaping, especially in organic forms, we can state that there is no stability, no resting or completing—but rather a fluctuation of all phenomena.” (pp 55, my translation and emphasis.)
genus *Homo*. Here, therefore, studies are reviewed that are based on (2) embryological data sets. Generally, the methodological approaches taken to the analysis of the ontogeny of modern individuals and the fossil record differ strongly and accordingly have different meanings for the study of evolution (MacPhee 1981).

Focusing mainly on current primatological and paleoanthropological aspects, the far-reaching influence of (3) Bolk’s fetalization hypothesis is retraced. Gould’s (1977) interpretation is reconsidered (4), not only based on modern studies but also on traditional work that nowadays maintains only a shadowy existence, although its explanatory power is astonishing. As one may well imagine, any review of the ontogeny–phylogeny question must at present be incomplete. However, *gutta cavat lapidem, non vi sed saepe cadendo* (constant dripping wears away the stone).

### 3.2 Comparative embryology and evolutionary developmental biology

#### 3.2.1 Karl Ernst von Baer and *Gallus domesticus*: the beginnings of comparative embryology

Nineteenth-century comparative embryology lies at the origin of evolutionary developmental biology or, more briefly, *evo-devo*. Von Baer’s and Haeckel’s works are the most popular examples of that period, and these authors’ “laws” describing the general development of organismic form are of great interest.

Karl Ernst von Baer, a pupil of Ignatius Döllinger, a professor at Würzburg, is known as the founder of embryology as a scientific endeavor. Although representatives of German transcendentalism had provided some insights into the field of embryology, it was only in 1828 that von Baer’s *Über die Entwickelungsgeschichte der Thiere: Beobachtung und Reflexion* appeared in print and made even contemporaries recognize him as the founder of embryology. In the first volume of his masterpiece, von Baer concentrated on the development of the chicken (*Gallus domesticus*), but he also bore general laws of development in mind. He worked with dissecting needles and a simple microscope: the “Scholia” describe the deductions he made. The accuracy and minuteness of his fundamental observations is absolutely astonishing. Russell (1982 p 114) was unable to hide his admiration: “His account of the development of the chicken is a model of what a scientific memoir ought to be . . . .”

Von Baer’s ideas incorporate the truly important distinction between the *type* (Wiesemüller et al. 2002) of organization (= the structural plan) and the *grade* of differentiation (modifications of this plan). The aim of comparative anatomy to
reveal group-specific Baupläne now had a prominent new tool by integrating embryological data.

As Charles Darwin was not a professional morphologist, it was others who introduced evolutionary thinking into the realm of comparative embryology. Ernst Haeckel’s formulation of the biogenetic law (ontogeny as the short and rapid recapitulation of phylogeny) presents a radicalized phylogenetic approach. Recapitulatory ideas were not new since Müller (Russell 1982) had already supported a similar hypothesis in 1864. Yet Haeckel’s verve and passion—very striking in a commemorative speech in 1909 (Das Weltbild von Darwin und Lamarck), on the occasion of the 100th birthday of Charles Darwin, favoring Goethe’s monistic world view as being the ultima ratio—made it famous. The interpretations of heterochrony and its implication for paleoanthropology are discussed later on. However, how does today’s evolutionary developmental biology reflect the ideas of von Baer and Haeckel?

3.2.2 The newcomer: evolutionary developmental biology

3.2.2.1 Von Baer and Haeckel—outmoded?

The fancy term evo-devo biology represents an emerging field (Gould 2002; Carroll 2005) that has been specially featured in semi-popular journals such as PNAS (2000) or Nature (2003). It refers to the quest by evolutionary biologists to understand how organisms change shape and form. Hall (2002 p 8) explained that “… evolutionary developmental biology is more than a name for an emerging subfield of biology. It is a reflection of a level of analysis, synthesis, and understanding not possible through the study of evolution or development alone.”

So how are the laws of von Baer and Haeckel interpreted nowadays? Gould (1977) supported von Baer’s explanation and regarded it as being essentially correct while Haeckel’s law is incorrect. Arthur (2002, p 757) disagreed and argued that when comparisons are made between different levels of complexity, a pattern emerges that is broadly (although only in a very imprecise way) recapitulatory. The déjà vu occurs by recapitulating levels of complexity rather than precise morphological details. Haeckel and von Baer are both right in assuming that “evolution leads both to embryonic divergence and, in some lineages, to a lengthening of the ontogenetic trajectory leading to more complex adult phenotypes with greater numbers of cells, their embryos passing through simpler, quasi-ancestral forms.”

Sander (1983) defined a “phylotypic” stage by describing a point of maximum similarity and a succeeding period of divergence. In this scheme, von Baer’s
principle of divergence only applies after this stage. Richardson et al. (1997) revealed a phylotypic period, rather than a stage, by screening more vertebrate species: this supports a broader comparative view. The hourglass model of development (Duboule 1994) might prima facie have reduced the explanatory power of von Baer. We should, however, be aware that this is a different kind of hourglass, the point of constriction being close to the beginning (Richardson 1999).

3.2.2.2 Homeobox-Pandora’s box for the integration of biological subdisciplines?

Lewis (1978), Nüsslein-Völlhard and Wieschaus (1980), and others (see also Lemons and McGinnis 2006) have revealed the meaning of homeobox genes and their importance for investigating the Bauplän. One application of this discovery which causes headaches for many scientists (Kuratani 2003) is the vertebrate cranium: is it a novelty that lies anterior to the head of a prevertebrate organism, or is it homologous to a special region of the amphioxus nerve cord? Holland et al. (1992) recognized a homology based on a comparison of expression patterns of AmphiHox 3 (an amphioxus Hox gene) and Hox-2.7 (the supposed mammalian homolog) and consequently denied the vertebrate brain as representing a novelty of the animal kingdom.

Hillis and Moritz (1990 p 502) emphasized that the power and the rapid development of these techniques “has produced an euphoria in evolutionary biology, because so many new problems can be addressed, it is a commonly held misconception that all evolutionary problems are solvable with molecular data . . .” Nielsen (1995) worried that without morphological characters the molecular data can produce only “naked” trees. Müller’s (2005) review explained inter alia the importance of a comparative morphology program as a prerequisite for an evo-devo synthesis.

Furthermore, Conway Morris (2000 p 4429) warned about “the risk of losing the overall evolutionary context. […] Not only that, but there are intriguing mismatches between genomic architecture and bodyplan complexity.” He pointed out that in all likelihood, a substantial proportion of the metazoan genome was available well before the Cambrian explosion and that a corresponding genetic architecture of genes and bodyplans is required, although he admits that we are still far from understanding either their interconnections or evolution. Arthur (2002) also met the challenge by demonstrating the change of tendency from general laws to specific pathways. He thus called attention to emerging concepts that integrate the overwhelmingly complex data.
As there is no one-to-one correspondence between genotype and phenotype, another important aspect of the problem lies in the interaction of genetic and nongenetic factors that act in different ways upon gene expression and create phenotypic diversity during development and evolution (Hall 1990, 1998b, 2002). Thus begins an appreciation of epigenetics. Goodwin et al. (1983), Raff (1996), and Hall (1998a–c) have called attention to the fact that change in development and evolution must be considered as an interaction of several “biological levels” so that consequently a hierarchical structural analysis is needed.

The timeless stimulus of Carl Gegenbaur—once called the most important morphologist in the world—and his legacy for twenty-first century evolutionary developmental biology lies in his methodological reflections about the relationship between embryology and comparative anatomy. Gegenbaur’s emphasis of careful and detailed observation over tempting and far-reaching speculation should be the *aurea mediocritas* (the golden mean) in our fast-moving world. The modern scientific endeavor faces therefore similar challenges to those of the nineteenth-century evolutionary morphologists, “namely to distinguish between several possible phylogenetic scenarios” (Laubichler 2003 p 29).

As to the formal integration of evo-devo with neo-Darwinian theory not much progress has yet been made. The way toward a unified theory, however, seems to be open, and the stimulation of the biosciences through evo-devo biology is quite evident (von Dassow and Munro 1999; Müller 2005).

### 3.2.3 Primates and supreme public servants of the Greek ancient world

#### 3.2.3.1 Primates and their supraordinal relationships

Although primate origins and supraordinal relationships are discussed twice in Volume 2 (Chapter 1 on morphological and Chapter 2 on molecular data), I would like to mention some studies that have used ontogenetic data in this context. According to Hofer, one of the ultimate goals of primatology (Spatz 1964) is the elucidation of the phylogenetic position of primates compared to other mammals. Gregory (1910) formulated the concept of the Archonta, which unites Chiroptera (bats), Dermoptera (colugos), Menotyphla (Macroscelidea = elephant shrews and Scandentia = tree shrews), and Primates into one single superorder. Later on, modified versions of this hypothesis excluded the Macroscelidea (Novacek and Wyss 1986), while Adkins and Honeycutt (1993)
surprisingly favored a revival of this grouping based on molecular data (COII gene). Even after the Hennigian revolution (1950), many morphologists confirmed the traditional version of primate supraordinal relationships by defining synapomorphies (Hooker 2001). Noncladists, such as Szalay (Szalay and Drawhorn 1980; Szalay and Lucas 1993), supported the evolution and diversification of archontans in an arboreal milieu. The approach is based on the aim of “Darwinian evolutionary classification” to include both adaptive similarity and monophyly sensu Bock and von Wahlert (1965). Critical comments can be found in Grande and Rieppel (1994).

Murphy et al. (2001), however, proposed the new superorder “Euarchontoglires,” based on nuclear and mitochondrial gene sequences of 42 placental specimens. This new grouping (Asher et al. 2005; Nishihara et al. 2006) consists of the Euarchonta (=Dermoptera + Primates + Scandentia) and the Glires (=Lagomorpha + Rodentia). Surprisingly, bats are excluded and do not seem to be closely related to primates. MacPhee (1993 p 372) already noted (based on Adkins and Honeycutt 1993) that “… something is pulling the rodents toward the primates in this data set. . . .”

These radical changes in primate supraordinal relationships consequently deny the Volitantia hypothesis (Illiger 1811), which favors a sister group relationship of bats and colugos (Leche 1886; Thewissen and Babcock 1991; but see Beard 1993). Wible and Martin (1993) documented that the ontogeny of the tympanic floor and roof does not provide any characters distinguishing all extant archontans from other eutherians. Actually, Archonta (archontans were supreme public servants of the Greek ancient world) has Scala naturae written all over it and represents a vehicle to explain the existence of flying mammals (Chiroptera) via a gliding intermediate stage (Dermoptera) in the absence of appropriate fossils (see also Sears et al. 2006). It should be emphasized that the concept of Scala naturae was long developed before the theory of natural selection (Martin 1973). Darwin (1859) promoted the view that nature does not make leaps—Natura non facit saltum—in order (1) to fill the gaps in the fossil record and (2) to strengthen his intellectual position (Schwartz 2000). Although Darwin’s motives are plausible, accepting the Volitantia concept might be an immediate consequence of the emerging battle against supporters of divine creation. Rasmussen (2002 p 7) specified in a more diplomatic manner: “However, it is fair to say that at this juncture we do really not know if primates are more closely related to Scandentia, Plesiadapiformes, Chiroptera or Dermoptera. These four orders are conveniently lumped together as ‘archontan’ in what may be a true clade but which for lack of unambiguous evidence is often used as an informal grouping.” Faute de mieux: chimeric archontans? In the context of primate evolution, some important examples of cranial and postcranial anatomy are presented here.
3.2.3.2 The myth of primate entotympanics: consulting embryological data and its phylogenetic implications

It is now more than a century since embryological studies [the Reichert-Gaupp theory, refuted by Otto (1984)] demonstrated the homology of the mammalian malleus and incus with the articular and quadrate bones which formed the ancestral jaw joint of gnathostomes. This tremendous transition can be traced in fossils by comparing basal synapsids through therapsids to early mammals. A fetal mammal shows that the angular (= tympanic), articular (= malleus), and quadrate (= incus) develop in the same positions they occupy in the cynodont skull (Allin 1975; Maier 1987). The importance of new fossils (Rich et al. 2005), however, is demonstrated by Martin and Luo (2005): the separation of the middle ear bones must have evolved independently among the therians and the monotreme mammals. The middle ear and surrounding basicranium have played a decisive part in mammalian systematics over the past years (e.g. Sánchez-Villagra et al. 2002).

In 1979—2 years before Auditory Regions of Primates and Eutherian Insectivores was published—R.D.E. MacPhee presented a new interpretation of the disputable issue of “primate entotympanics.” Not all mammals show these mysterious skeletal elements. As otic characters are essential for primate taxonomy, this was a potential criterion for distinguishing primates from their relatives [e.g., colugos (Figure 3.1) and tree shrews]. Mivart (1881) defined this specific element as “entotympanic,” while Wincza (1896) introduced the term “metatympanic” (van Kampen 1905). A few influential morphologists (van Kampen

![Figure 3.1](image-url)

Top: Fetal Cynocephalus volans (Dermoptera). Cranial length 41 mm, frontal section. Note the entotympanics. c.E = caudal entotympanic, C.t. = cavum tympani, F.r. = Fenestra rotunda, M.m. = Manubrium mallei, P = petrosal, R.m.a. = Recessus meatus acustici externi, Tu.K. = Tuba auditiva-cartilage, Ty = tympanic, x,y = cartilage. Sections have a thickness of 25 μm. Not to scale. (Modified from van der Klaauw 1922). Center: Late-fetal Cynocephalus variegatus (DUCCE 806). Crown-rump length 136 mm. It shows a frontal section through the promontorium in front of the tegmen tympani. Arrowheads point to branches of the internal carotid nerve running in a transpromontorial position. Scale bar = 0.33 mm. “Cat” = fused cartilage of the auditory tube and rostral and caudal entotympanics, bo = basioccipital, co = cochlea, ct = cavum tympani, e = ectotympanic, eam = external acoustic meatus, pe = petrosal, pr = promontorium of petrosal, t = tympanic membrane. (Modified from Wible and Martin 1993, © Plenum Press). Bottom: The next step. Frontal section of a juvenile Cynocephalus volans-specimen, of 145 mm crown-rump length, from the collection of the Institute of Systematic Zoology in Tübingen. It illustrates the ossification of the fused cartilage of the auditory tube and the rostral and caudal entotympanic (o’“cat”). Hunt and Korth (1980) reported but they did not illustrate the fate of this important anatomical detail. Sections have a thickness of 40 μm. Not to scale
Figure 3.1 (continued)
1905; van der Klaauw 1931) already championed the existence of primate entotympanics.

Van der Klaauw (1922) published an ingenious work (Über die Entwicklung des Entotympanicums) in which he made a strong case for two different types of entotympanic, rostral and caudal. Developing in the anteromedial corner of the membranous tympanic floor, the rostral entotympanic grows posteriorly. Unlike the tympanic processes, entotympanics grow and develop within the fibrous membrane of the tympanic cavity (MacPhee 1979).

Starck (1975 p 143) reported for Tarsius that the existence of an entotympanic is not yet proven. In the younger stage, the tympanic region does not show any peculiarities and an entotympanic cannot be detected. However, an older specimen showed a floor of the middle-ear cavity that is formed by endochondral bone. It was closely connected with the otic capsule, but it showed a rostral extension near the auditory tube: “The ossified bone still contains some cartilaginous tissue, and this would indicate the presence of a true entotympanic, since the petrosal components of the floor are usually formed by periosteal bone. These results are in accordance with the findings of van Kampen (1905).” (My emphasis.) According to MacPhee (1979), primate tympanic floor elements do not develop like any known entotympanic but, rather, like other tympanic processes. Prenatal Microcebus demonstrates secondary cartilage in the rostral tympanic process of the petrosal, which is interpreted as an embryonic adaptation—the explanation of the primordial fusion of once separate entities is no longer required. The hypothesis of a suppressed entotympanic is made more unlikely by the endochondral development of the caudal tympanic process of the petrosal (contra Starck 1975). To quote MacPhee (1979 p 43): “Therefore, with regard to the constitution of the primate ventral wall, and with some necessary violence to Newton’s quip, non fingo ossa - I posit no bones.” Eureka, a new primate characteristic was identified via the careful interpretation of ontogenetic data.

3.2.3.3 Postcranial ontogenetic data and the origin of primates

Stafford and Thorington (1998) and Hamrick (2001) presented important data on the hand proportions in developing and adult mammals. Using a ternary plot (Hamrick 2001), relative metacarpal, proximal, and intermediate phalanx lengths among fossil and extant taxa deliver an elegant possibility of distinguishing primates from other “archontan” mammals. Primates differ from flying and gliding mammals in having much longer proximal phalanges relative to their metacarpals and are unique among the sampled mammals in having elongated proximal phalanges relative to their metacarpals. A comparative analysis of hand
development in the mouse lemur *Microcebus murinus* and other meta- and
eutherian mammals reveals that “interspecific variation in relative digit and
metapodial proportions has high-developmental penetrance; that is, adult
differences are observed at early ontogenetic stages” (Richardson 1999 p 348).
Hamrick’s (2001) results suggest an evolutionary scenario that describes an
“invasion” of the fine branch niche based on a hand with a short palm and
long fingers yielded by a change in digital ray patterning and segmentation.

Recent advances in developmental genetics elucidate patterns of postcranial
growth in primates. Another study is based on a comparison of developmental data
of CD1 mice fetuses and Rhesus macaques: Hallgrimsson et al. (2002) demon-
strated the evidence for morphological integration of the limbs as serially homolo-
gous structures by reporting the covariation structure of forelimb and hindlimb
skeletal elements. This proves that link structures between the limbs are caused by
developmental modules, producing the covariation that would be needed to be
overcome by selection for divergence in fore- and hindlimb morphology.

Since primates have more distally concentrated limb mass than most other
mammals, Raichlen (2005) studied the unique kinematics of primates by testing a
longitudinal ontogenetic sample of baboons (*Papio cynocephalus*). He concluded
that the evolution of primate quadrupedal kinematics was tied to the evolution of
grasping hands and feet.

### 3.2.4 The impact on paleoanthropology

#### 3.2.4.1 Bolk’s fetalization hypothesis: its successors and critics

**Forever young?** Many contributions have emphasized the relevance of phylo-
genetic conclusions from ontogenetic information (Minugh-Purvis and
McNamara 2002). One of the most influential books on developmental change
Tuttle’s (1978 p 287) review of this book was not rhapsodic: “Perhaps the author
attempted too much in this chubby volume [. . .] Time will tell whether it is in
fact a hemicentennial classic as implied on the dust jacket.” Well, in the meantime
it has become probably one of the most frequently cited compendiums. Howell
(2002 p xi) commented that “its effect was immediate, substantive and far-
reaching.” Looking briefly at the bibliographies of modern studies often gives
the impression that the consideration of developmental change in human
evolution began in 1977 (Coqueuniot et al. 2004). Here I focus partly on some
of the “ancient” morphological studies that negate “essentially neotenous” ideas,
to show how profound their explanatory power really is.
Why assume an *impact* on paleoanthropology? The ideas of Louis Bolk, a Dutch anatomist, have in fact had an enormous influence on scientists working in many different fields. The paleontologists Beurlen and Schindewolf (1936, 1950) supported a phenomenon called “proterogenesis” by pointing out that some evolutionary lineages that are present in successive strata may be interpreted as a process of maturing of former embryonic or postembryonic form levels. I mention these thoughts—although they do not deal with anthropological questions—because they show that Bolk’s thoughts are part of a greater, speculative construct of evolutionary ideas. Portmann (1960) already assessed the situation by claiming that criticism of Bolk’s considerations has to be criticism of the entire construct and argued that it is still in progress and may not be considered completed.

As Starck (1962) argued, Hilzheimer (1926, 1927) and others have pointed to morphological and physiological data to explain the principle of fetalization. Starck (1962) traced the hypothesis of neoteny back to Strickland and Melville (1848), but Bolk was the one who applied it to human evolution. A sequence of papers (the version of 1926 being the most frequently cited) takes us away to a non-Darwinian construct. So which are the essential elements?

Bolk (1926 p 5) split human characters into (1) primary and (2) consecutive features. Primary characters are those products of developmental factors that caused the origin of human morphology. Consecutive characters, on the other hand, are phenomena of bipedal adaptation. Hence, the *primum mobile* of human evolution is not bipedalism, the “secondary” characters of which strictly follow functional aspects. Bolk (1926) considered the primary human characters to be: (1) reduction of body hair, (2) form of the external ear, (3) the epicanthic eyefold (=Mongolian eyefold), (4) loss of pigmentation in skin, (5) orthognathy, (6) foramen magnum in a central position, (7) a long persistence of cranial sutures, (8) subcerebral position of orbits, (9) high relative brain weight, (10) position of the spinal column relative to the cranial cavity, (11) women’s labia majora, (12) structure of hand and foot, (13) form of the pelvis, (14) women’s sexual canal in a ventral position, (15) multipapillary kidneys, and (16) the branching pattern of the arch of the aorta [the last two characters are not mentioned by Gould (1977)]. What is the common denominator of these characters?

The characters listed by Bolk are phenomena which temporarily appear during primate ontogeny. Although Bolk (1926 p 44) differentiated the problem by separating (1) the relatives of *Homo sapiens* and (2) the development of human shape, as Slijper (1936 p 504) explained, he advocated the idea that our ancestor must have been an *extant* primate species. Characters of human fetalization consequently represent persisting ontogenetic primate characters. Human
ontogeny therefore demonstrates conservative traits, while humans’ primate ancestors showed “propulsive” (=advanced) characters. Bolk’s (1926 p 26) bottom line is: *H. sapiens* represents a sexually mature primate fetus. However, how did he explain the inhibitive force that fixes man’s physical appearance at a certain point in time?

“The obvious answer is: The slow progress of his life’s course” (Bolk 1926 p 470) and the fact that “human life progresses like a retarded film” (Gould 1977 p 360). Bolk (1926 p 38) asserted that the development of dentition, consciousness, and the late closure of cranial sutures act as indicators of a dominant retardation phenomenon. The chain of causes starts with the modification of the endocrine gland function (for a modern hypothesis see Crockford 2002) by *internal* alteration, not by external factors of the environment (Bolk 1926 p 22).

Slijper (1936), another Dutch scientist, published an outstanding analysis that considered cetacean relationships, the fetalization hypothesis, and the clarification of fundamental terms. Ironically, Gould (1977 p 365) called Slijper’s criticism “famous,” which is quite euphemistic since even the German-speaking Starck (1962) complained about it as not being easy accessible and often ignored. One major problem of Bolk’s idea is the *subjective* splitting of primary and consecutive features. Slijper (1936 p 509) recapitulated Bolk’s scientific career and stated: “...we get the impression that Bolk did not present primary characters (mostly human) at first and discovered their fetal character afterwards, but rather observed a contrarian procedure: he discovered fetal characters and defined them subsequently as primary. This explains the remarkable correlation of primary features with fetal phenomena and diminishes its objective value.” (My translation.) Slijper also denied any general neotenous influence on human ontogeny.

Two prominent morphologists concerned with primordial cranial studies were Benno Kummer and Dietrich Starck. In 1962, they published the first modern study on fetal *Pan troglodytes* (Figure 3.2). Starck and Kummer followed Hofer (1958, 1960) in distinguishing basal and prebasal kyphoses. Gould (1977 p 378) excellently summarized their findings thus: (1) all fetal mammals have a prebasal kyphosis at the junction of the presphenoid and ethmoid bones (a bending with the concave side toward the body, as opposed to a lordosis), (2) this kyphosis decreases during ontogeny, the sphenoethmoidal angle opens out, and the face comes to lie in front of the cranium, (3) while the prebasal kyphosis develops within the basicranial axis during human ontogeny, a different kyphosis develops between the basisphenoid and presphenoid bones at the level of the dorsum sellae. This second kyphosis produces a secondary decrease in the sphenoethmoidal angle following the earlier increase conditioned by straightening of the prebasal kyphosis, (4) the “fetal” value of the
sphenoethmoidal angle in human adults does not reflect the retention of a fetal condition but arises from development of the new, sellar kyphosis. It is a new feature—not a paedomorphic retention.

Amazingly, Gould (1977 p 379) concluded: “These authors have used this single contention as the basis for a campaign against the hypothesis of fetalization . . .” A single contention? A *campaign*? To be blunt, Gould himself started a campaign. In relation to Bolk’s explanation of skull development, Portmann (1960 p 586) already commented that “… skull development is a complex issue which makes Bolk’s solution suspicious.” (My translation.) Reflecting the development and evolution of the human chin, Vogel (1964) warned against too “localized” a view and called for the consideration of the complexity and interaction of all developing skull components. Schwartz and Tattersall (2000) revisited the presence of a chin in hominins and examined the importance of developmental epiphenomena.

Furthermore, Gould (1977 p 379) claimed that the “… tradition of excellence in descriptive morphology is combined with a general avoidance of quantification, and this may have hindered a full assessment.” He might have
overlooked an essential part of Starck and Kummer’s (1962 p 213) paper because “these findings can be characterized as quantitative...”: (1) different relative sizes of neurocranium and auditory capsule, (2) tegmen tympani, (3) frontal nasal region, (4) canaliculus chordae tympanic posterior, (5) commissura orbitonasalis, and others. Gould (1977 p 384), however, did not fall into the Bolkian trap of an all-or-nothing law. Instead, he argued that “most of the classic ‘exceptions’ to human paedomorphosis are really consequences of retarded development,” which Gould described as being the central phenomenon of our heterochronic evolution. Yet his ideas represent an analytic continuation of the Bolkian hypothesis.

Starck and Kummer (1962) did not exclude retardation (as in the commissura orbitonasalis) as an important factor of human development, but they emphasized that accelerations (e.g., the earlier closing of the intermaxillary suture in Homo) as well as deviations (e.g., the basicranium), should influence specific developmental processes. Starck’s (1962 p 23) summary revealed that the principles of human evolution cannot be understood through Bolk’s hypothesis: Important structures of the skull, very often taken as a result of fetalization, are indeed progressive compared with the pongid skull. It is emphasized that the bending of skull base in man and apes is absolutely different, caused by different morphological structures. Identity of causal factors is not established, if we find external similarities, such as the same size of angles, of relative measurements or indices. This may happen by addition of completely different components.

This statement seems not to be a furor teutonicus but rather a well-balanced point of view. Hence, morphometrics might work, but the comparison of morphological details must occur in a correct manner. How do contemporary anthropologists interpret morphological changes of this important cranial region?

**Developmental aspects concerning the evolution of the human cranial base** The cranial base represents the oldest component of the vertebrate skull (De Beer 1985). Thus this “conservative” structure is profoundly important in reflecting man’s phylogenetic history and comparing primates to reveal essential aspects of human evolution. The keystone of the primate skull is definitely the basicranium. Several regions, such as the upper airway, the brain, and other parts, impinge upon one another here and consequently interact during ontogeny (Moss et al. 1982; Dean and Wood 1984; Lieberman et al. 2000). Biomechanically, the cranial base supplies a platform on which the brain develops and around which the face grows. The cranial base also forms a bridge connecting the cranium with the rest of the corpus: providing conduits for all circulatory and vital neural connections, articulating with the mandible and the vertebral column, forming the roof of the nasopharynx, and connecting the sense organs in the skull. Lieberman et al. (2000
p 120) stated that “the shape of the cranial base is therefore a multifactorial product of numerous phylogenetic, developmental, and functional interactions.”

Scientists are confronted with the problem of complicated circumstances in studying this truly important region. It is not only complexity that matters but also problematic ways of measuring. Furthermore, the fragmentary nature of fossil remains causes major difficulties. Novel analytical techniques, however, have helped to engross our thoughts over the past years. Different hypotheses exist that deal with ontogenetic spatial processes and their phylogenetic implications. I mainly follow Jeffery (2003) in reviewing some of the most popular versions. The general spatial-packing hypothesis states that the modern human basicranium is caused by a short cranial base and an enlarged brain. Ross and Ravosa (1993) and Ross and Henneberg (1995) revealed significant positive correlations between increases of relative brain size and cranial base flexion across adult primate taxa: correlation of increasing relative brain size with (1) a coronal reorientation of the petrous bones across extant primates (Spoor 1997), (2) a cranial base flexion using different measurements and landmarks (Spoor 1997; McCarthy 2001), and (3) a cranial base flexion after controlling for the influence of phylogenetic correlations (Lieberman et al. 2000). Enlow and colleagues (Enlow and Hunter 1968; Enlow 1976, 1990) also attempted to demonstrate a determination of cranial base flexion through increases in relative brain size during primate development. Jeffery and Spoor (2002) could not verify these authors’ arguments. They analyzed specimens from 10 to 29 weeks of gestation and documented that petrous orientation and cranial base angulation do not correlate with increases in infratentorial volume relative to posterior cranial base length.

The infratentorial spatial-packing hypothesis has been revitalized by Dean (1988), who argued that having coronally oriented petrous bones and a highly flexed basicranium poses the spatial problem of fitting an enlarged cerebellum on a short posterior cranial base. Jeffery and Spoor (2002) showed that ontogenetic data, collected during the second and early third trimesters of human prenatal development, do not support Dean’s (1988) claim. They indicate that the petrous orientation and cranial base angulation do not correlate with increases in infratentorial volume relative to posterior cranial base length.

The influence on skull form of patterns of brain growth is addressed by two interesting models. Hofer (1969) and Lieberman et al. (2000) favored the brain shape hypothesis, while Ross and Henneberg (1995), Chklovskii et al. (2002), and Sporns et al. (2002) supported a neural-wiring hypothesis. These ideas have in common a suggested necessary change in brain topography to maximize cognitive efficiency by reducing neural wiring lengths. The resulting spatial

Moss et al. (1956) suggested that brain topography is shaped by differential encephalization patterns which lead to developmental changes in posterior cranial fossa morphology.

A few studies (Guihard-Costa and Larroche 1990, 1992; Jeffery 2002) on the human fetal brain showed greater increases in expansion of the supratentorial portion (containing the cerebrum) compared to the infratentorial portion (consisting of cerebellum and brainstem). However, the independence of human cranial base angulation and petrous orientation of changes from the volumetric proportions of the brain between the ages of 10 and 29 weeks gestation are corroborated by Jeffery and Spoor (2002).

Jeffery (2003) tested the key hypotheses by imaging fetal samples of *Alouatta caraya* and *Macaca nemestrina* using high-resolution MRI. He noted marked increases in brain size, especially “disproportionate increases in the size of the cerebrum” (p 281), disproportionate growth of the anterior midline basicranium compared with the posterior midline basicranium, coronal reorientation of the petrous bones, and cranial base retroflexion. Contrary to the spatial-packing hypotheses, increase in relative brain size is not accompanied by flexion of the midline basicranium. Retroflexion is documented for the cranial base in both taxa. There is also little evidence supporting the spatial-packing hypothesis for the fetal period of the howler monkey and macaque due to significant and “seemingly” consistent associations with petrous orientation arise based on background covariations with somatic growth. Jeffery (2003) therefore suggested that laryngeal size might be the reason for basicranial retroflexion. He finally compared it to human fetuses and concluded that the establishment of notable interspecific differences in the basicranium occurs much earlier than in the phase he studied.

Craniofacial growth patterns have been studied by several scientists (Giles 1956; Shea 1983, 1985a, b; Jungers and Hartmann 1988; Ravosa 1991, 1992; Zumpano and Richtsmeier 2003; Cobb and O’Higgins 2004; Mitteroecker et al. 2004). Lieberman et al. (2000) provided a comprehensive review of primate cranial base studies. As Zumpano and Richtsmeier (2003) pointed out, many previous studies documented postnatal growth processes, usually beginning with
growth during the juvenile period. The infant growth period has been incorporated by Ravosa (1992), Richtsmeier et al. (1993), or Shea (1983), while Zumpano and Sirianni (1994) compared fetal to postnatal craniofacial growth patterns. Collections of fetal primates very often do not contain representative specimens (Zumpano and Richtsmeier 2003 p 340). Yet it is desirable to attempt an integration of these stages since only a completely documented ontogeny delivers deeper insight to reveal whether heterochronic processes are responsible for the modifications that have occurred between human and nonhuman primates.

Zumpano and Richtsmeier (2003) investigated, for the first time, growth-related shape changes in the fetal craniofacial region of humans and pigtailed macaques (M. nemestrina), using three-dimensional comparative analysis via cross-sectional samples of CT image data. As they emphasized, a long tradition of studies concentrated on examining the sites of growth of the cranial base, the sites of cranial base flexure, and the determination of the cranial base angle (Bjork 1955; Ford 1956; Dubrul and Laskin 1961; Houpt 1970; Lavelle 1974; Bosma 1976; Lestrel and Moore 1978; Moore 1978; Sirianni and Van Ness 1978; Sirianni and Newell-Morris 1980; Ross and Ravosa 1993; Ross and Henneberg 1995; Zumpano and Richtsmeier 2003). Zumpano and Richtsmeier (2003) showed that decreases in human cranial base length are achieved through the differential growth of posterior and anterior elements. The length of the posterior cranial base decreases, while increases occur in the length of the anterior cranial base. They further argue that a cranial base angle decrease may lead to a total reduction in cranial base length in human fetuses. At a comparable stage, the fetal macaque cranial base does not show a corresponding reduction (increased basicranial flexion). The associated distinctiveness of the differences in midfacial growth and the progression of prenatal cranial base flexion are said to be a factor separating these two species. Zumpano and Richtsmeier (2003) also contradicted Bjork (1955) and Ford (1956) in noting a basicranial flexion—not a constant angle—during the fetal period. They further support Lestrel and Moore (1978), and Sirianni and Newell-Morris (1980) are also supported in assuming a constant macaque cranial base angle during fetal growth, although they report a lesser angle (153°). The human anterior cranial base undergoes more relative growth than the macaque anterior cranial base. For the posterior cranial base, no significant growth differences between these two species are observed. Zumpano and Richtsmeier (2003) speculated that the increases in relative length of the anterior cranial base in humans may reflect the faster rate of growth of the frontal lobes of the cerebral cortex in humans relative to macaques (Enlow and Hunter 1968; Moss and Salentijn 1969; Moss 1973; Sirianni and Newell-Morris 1980) and conclude, based on their own observations and the studies of Anemone and Watts
(1992) and Swindler (1985), that midface differences between humans and macaques reflect a delayed rate of maturation of the human deciduous dentition or an accelerated rate of development. In a tabula rasa manner, Zumpano and Richtsmeier (2003) supported earlier investigations in suggesting the occurrence of shape changes within the fetal craniofacial complex during the last trimester of fetal growth (Grausz 1991; Plavcan and German 1995) rather than assuming an isometric growth process that is, e.g., characterized by size increase without corresponding shape change (Mestre 1959; Houpt 1970; Kvinsland 1971a, b; Lavelle 1974; Moore and Phillips 1980; Sirianni and Newell-Morris 1980; quoted from Zumpano and Richtsmeier 2003). Zumpano and Richtsmeier (2003 p 349) finally concluded that “fetal macaques and humans do not share a common pattern of relative growth of the craniofacial complex, both species undergo increases in mediolateral dimensions (widening) of the skull and increases in palatal and anterior cranial base length.”

One of the ultimate goals in paleoanthropology is to reveal the precise relationship of humans to the great apes, our closest living relatives. Morphological data favor the monophyly of the African great apes, while molecular biology unites humans and chimpanzees (Mann and Weiss 1996; Ruvolo 1997; Enard et al. 2002; Kaessmann and Pääbo 2002). Wildman et al. (2003) even placed chimpanzees within Homo based on molecular data. Pääbo (1999) emphasized the importance of investigating a few genes that are responsible for specific effects during ontogeny (or in adulthood) instead of concentrating on chromosomal rearrangements or the accumulation of point mutations. Hence, Mitteroecker et al. (2004 p 680) stated that “as it is difficult to study gene expression on a molecular level for the whole organism, we confine ourselves to the study of the morphological effects of gene expression during ontogeny.” They therefore created a shape space where each specimen (that is, its landmark configuration) is represented by a single point. In this context, an ontogenetic trajectory corresponds to the ontogenetic sequence which belongs to one species within this space. As Klingenberg (1998) or O’Higgins (2000a, b) showed, geometric contrasts among ontogenetic shape trajectories distinguish the development of different species. Geometric morphometrics is a promising and complex method of collecting and interpreting data based on morphological patterns (Bookstein 1991; Marcus 1996; Dryden and Mardia 1998; Slice 2005).

Some hominid craniofacial growth studies, applying geometric morphometrics, found more or less parallel trajectories from dental stage I (which corresponds to the first permanent molar) to adulthood (Ponce de León and Zollikofer 2001; Penin et al. 2002). The development of hominid cranial morphology consequently diverges from that of the other apes in an early postnatal or prenatal stage. However, O’Higgins (2000a; O’Higgins et al. 2001) confirmed
Richtsmeier et al.’s (1993) assumption of related species subsequently diverging after a similar period of early development. In a comprehensive study, Mitteroecker et al. (2004) measured landmarks and semi-landmarks in relevant specimens following a few days after birth to reveal essential insights into hominid ontogeny. Several principal patterns can be deduced from the set of ontogenetic trajectories. The authors tested three specific hypotheses: (1) “pure heterochrony” of human cranial growth relative to *Pan* is a valid interpretation if the ontogenetic trajectories are identical in shape space, (2) the divergence of human ontogeny corresponds to a similar developmental stage at which the great apes diverge among themselves, and (3) an early divergence of trajectories from common ontogeny could elucidate the considerable morphological differences between humans and great apes because early modifications in development explain drastic transformations of the adult form (Richardson 1999). Studying 206 adult and 62 subadult crania of *Homo sapiens*, *Pan paniscus*, *P. troglodytes*, *Gorilla gorilla*, and *Pongo pygmaeus*, Mitteroecker et al. (2004) collected three-dimensional coordinates of 41 homologous ectocranial anatomical landmarks on the face and cranial base. They demonstrated the expected pattern whereby the youngest specimens are much more similar than the adults (von Baer’s omnipresent discovery). Already at birth, human craniofacial morphology differs markedly from apes (p 692) “in accord with previous studies based on more traditional methods” (Starck and Kummer 1962; Dean and Wood 1984). The first hypothesis, in contrast, can be rejected because there is no sharing of a common ontogenetic trajectory. Penin et al. (2002) tried to revitalize the “neotenic theory” *sensu* Gould (1977 p 365). They do not, however, support a “general, temporal retardation of development” but rather stress that “all the bipedal traits studied, whether in the skull (basicranium) or postcranium (pelvis and femur, see above), do not result from neotenic processes but rather from structural traits” (p 61).

Additionally, the second hypothesis is falsified, and the third hypothesis is supported, by an earlier divergence of the human growth trajectory from the common hominid allometry (Mitteroecker et al. 2004 p 692). The African apes also do not seem to be pure allometric variants of one single type. Mitteroecker et al. thus concluded (p 694) that “pure heterochrony does not sufficiently explain human craniofacial morphology nor the differences among the great apes.” McBratney-Owen and Lieberman (2003) also provide insight into the postnatal ontogeny of facial position in *H. sapiens* and *P. troglodytes* by emphasizing that the ontogenetic integration of complex phenotypes, such as the face, occurs on multiple levels of development, and they further speculate about the effectiveness of ontogenetic analyses for testing hypotheses about natural selection.
Ackermann (2005) investigated similarities in cranial covariation patterns by obtaining measurements from 677 crania of adult and nonadult African apes and sub-Saharan humans to locate underlying developmental and functional causes for the patterning. Defining the points of divergence of the covariation patterns can offer insights into the action of selection on development. Ackermann’s work shows that patterns of integration are similar (not identical) among adult African apes and sub-Saharan humans. Ontogeny documents a sharing of patterns, with each species showing contributions to total integration from the oral region as well as from the zygomatic and to a lesser extent the nasal regions. However, she documented important differences between apes and humans, stating: “In particular, the lower overall integration within and lack of covariance structure similarity among adjacent ontogenetic stages in early human ontogeny differs from what we see in the other apes. It is not entirely clear why this might be so, although it indicates that selection was working in this lineage - either on humans or the apes - to distinguish them not only in morphology, but in variation patterning” (p 195).

Quo vadis? Developmental aspects concerning the evolution of bipedalism I have already mentioned Bolk’s (1926 p 6) interesting ideas concerning human bipedalism “. . . since form became human the posture became upright” (my translation). Summarizing his growth studies on primates, Schultz (1924 p 163) asserted that “man in some respects is less specialized and has hence remained phylogenetically as well as ontogenetically more original and ‘primitive’ than various other primates.”

Structural and mechanical aspects of the locomotion of primates play a considerable role in many discussions of human evolution (Preuschoft 1971; Schaffler et al. 1985; Demes and Jungers 1993; Connour et al. 2000; Ruff 2002; see also Senut, Volume III). Schultz (1953) analyzed over 350 limb bone circumferences and related the results to locomotion. The evolution of bipedal walking has, naturally enough, inspired scientists to associate locomotor mode with the relative lengths of the forelimb and hindlimb bones (Schultz 1937; Napier and Napier 1967; Jungers 1982). Changes within the hominin lineage in the relative size of the upper and lower limb bones are indications of our transition to bipedality (McHenry 1978; Johanson et al. 1982; Wolpoff 1983; Hartwig-Scherer and Martin 1991; McHenry and Berger 1998; Asfaw et al. 1999; Richmond et al. 2002; Ward 2002).

A few French scientists (Berge 1998) have tried to integrate heterochronic processes into analyses of morphological changes during hominid evolution. These works have concentrated on such classic anthropological topics as the anatomy of the pelvis. Berge (1998 p 443) emphasized separating the debate on
neoteny by negating the idea “that identical heterochronic processes occur in skulls and postcranial skeletons, although we know that the growth of cranial and long bones differs in time, rhythm and velocity.” She studied the morphology of two adult pelves and a juvenile hip bone of australopiths, 60 juvenile and adult pelves of modern humans, and 150 juvenile and adult pelves of African apes. The results confirmed a marked difference of the pelvic growth pattern in African apes and humans as reflected in multivariate results, ontogenetic allometries, and growth curves. Two conclusions emerged: (1) a comparison of modern humans to juvenile and adult australopithecines reveals that a unique feature of *Homo* seems to be a prolonged growth in length of hindlimb and pelvis after sexual maturity, while pelvic growth of *Australopithecus* was probably closer to that of apes than to that of humans and that some pelvis traits of adult *Australopithecus* resemble those of neonate *Homo*. Furthermore, (2) at the time of human birth, the appearance of the acetabulo-cristal buttress and the cristal tubercle allows the addition of features, such as the attainment of a proportionally narrower pelvis, with more sagittally positioned iliac blades. In early childhood (as bipedalism is practiced), pelvic orientation and proportions change progressively, while other changes in proportions occur later with the adolescent growth spurt. Neonate *Homo* and adult *Australopithecus* show similar patterns concerning the position of the acetabulo-cristal buttress. This could suggest a later displacement during human evolution. Berge (1998) further documented a progressive displacement of the acetabulo-cristal buttress on the ilium occurring during human growth (from neonate to adult) and hominid evolution (from *Australopithecus* to *H. sapiens*). She finally suggested that evolution of pelvic morphology in hominids is based on a threefold process—predisplacement, acceleration, and time hypermorphosis—and rejected pure fetalization (p 457) by stating that “the present study demonstrates clearly that the concept of neoteny is irrelevant for the pelvis. The study rather implies an accelerated evolutionary process than a retarded one.”

Ruff (2003) examined the human development of femoral to humeral proportions using a longitudinal sample of 20 individuals measured radiographically at semiannual or annual intervals from 6 months of age to late adolescence and also included anthropometric data such as body weights or muscle breadths. A series of limb bone length proportion studies included ontogenetic data (Lumer 1939; Schultz 1973; Jungers and Fleagle 1980; Buschang 1982a; Shea 1983; Jungers and Susman 1984). Ruff (2003) focused on other limb bone dimensions. He compared his results with a cross-sectional ontogenetic sample of 30 baboons. The results document that femoral/humeral length proportions, which are already close to those of adults, are present in human infants, while characteristically femoral/humeral diaphyseal strength proportions only develop after the adoption of bipedalism (at about 1 year of age). Between the age of one
and three, a rapid increase in femoral/humeral strength occurs, and this is followed by a slow increase until mid-late adolescence (when adult proportions are reached). The femoral/humeral length ratio proportions slightly increases throughout growth. There is no apparent growth trajectory change at the initiation of walking and a small decline in late adolescence based on a later humeral growth in length. Also in early childhood, a sex difference in femoral/humeral strength proportions (but not length proportions) develops. Ruff (2003) therefore concluded that they must be largely independent of growth trajectories in strength and length proportions. Baboons (used as a baseline) show contrasting patterns of growth: much smaller age changes in proportions and particularly strength proportions. He therefore stated (p 342): “Comparisons with an ontogenetic baboon sample highlight the specific nature of the human developmental pattern.”

Returning to Adolph H. Schultz, we have an excellent example of a convert. In his youth, Schultz was stimulated by the neoteny hypothesis (see earlier). Following several studies (1953, 1973) although, he rejected Bolk’s idea and the theory of man’s neoteny.

3.2.4.2 Heterochrony in human evolution: a compilation

Repetitio est mater studiorum or as Schwartz (1999 p ix) commented: “... it would be foolhardy to cling unreservedly to a particular set of models and hypotheses without at least occasionally questioning their very bases.” In Sudden Origins, Schwartz reconsidered and discussed inter alia the different interpretation of the Taung child. While Raymond Dart was influenced by ideas of neoteny and concluded that his fossil occupied a missing link-position, Sir Arthur Keith drew a totally different conclusion and defined the Taung individual as an ape. Ironically, Keith’s results were also based on a developmental and even a neotenic chain of ideas (Figure 3.3).

Furthermore, Schwartz (1999) critically reviewed the suggestions of the Australian anthropologist Andrew Arthur Abbie, who equated neoteny and paedomorphism, and portrayed H. sapiens due to its long legs and a highly arched nose as gerontomorphic (=more differentiated from a fetal standard), although he generally described our species as paedomorphic (=little differences from a fetal standard). Abbie absorbed the heterochronic perspective but failed to sustain the argument that human morphological variability is not fixed to a limit and that any combination of features can be incorporated in the same individual.

Gould (1977, 1991 p 2) called attention to the difference between Haeckel’s heterochrony, which describes the pathway of development in an organ relative to
the pathways of other organs in the same animal, and current usage, which defines it as “the course of a trait relative to the ontogeny of the same trait in an ancestor (or related form).” Jena’s most famous zoologist was not really interested in elucidating evolutionary mechanisms as a method to explain the patterns of character states. He was rather interested in reconstructing natural history by applying biogenetic laws. Sir Gavin de Beer (1930) opened up new vistas by modifying Haeckel’s concept: any change in the timing of a character is compared to the same feature in an ancestor. This established the study of heterochrony within the modern synthesis (Gould 1991).

McNamara (2002 p 1) defined heterochrony essentially as “change to the timing and rate of development” which produces two major effects: *paedomorphosis* (if there is less growth during ontogeny, the descendant adult will resemble the juvenile condition of the ancestor) and *peramorphosis* (where the descendant undergoes greater development). Three different processes generate paedomorphosis and peramorphosis, respectively: (1) progenesis (prematurely truncated duration of growth in the descendant), neoteny (a lesser growth rate in the descendant than in the ancestor), and postdisplacement (delayed onset of growth) and (2) hypermorphosis (extension of duration of growth in the descendant), acceleration (an increase of growth rate in the descendant), and predisplacement (earlier onset of growth in the descendant). The whole organism can only be affected by progenesis and hypermorphosis, while the remaining aspects affect certain traits of the organism. McNamara (2002) further stated that peramorphosis and paedomorphosis are the products of varied processes rather than being processes in themselves. Hypermorphosis (extensions of the end of growth) and progenesis (contractions of the end of growth) are considered within a global context, “based on changes to the time of onset of sexual maturity and cessation of somatic growth, with the two frequently coinciding” (McNamara 2002 p 105).

Figure 3.3
The Taung child (left), compared to the skulls of comparably aged gorilla (middle) and chimpanzee (right). Dart’s desire was to show that the apes had begun to grow away from the juvenile state. The Taung specimen has no brow ridges, small jaws, and a very large brain (modified from Schwartz 1999, drawing by T. D. Smith, © J. H. Schwartz)
Different views have emerged on how large a role neoteny plays. While Gould (1977), Antón and Leigh (1998), and Montagu (1989) supported true paedomorphosis (neoteny), Shea (1988, 1989, 1992), McKinney and McNamara (1991), and McNamara (1997) favored some kind of hypermorphosis in time. Bogin (1997) suggested a new developmental stage in between (no heterochrony); Alba (2002) on the other hand, characterized paedomorphosis and peramorphosis as interpretative, not descriptive, terms. He emphasized the importance of modifying conventional clock models based on meaningful variables. Alba (2002) called for a double standardization (initial and final developmental stages) of ontogenetic trajectories and suggests a “complete” model including absolute age (at homologous developmental stages), shape, size, and behavior. As he admitted, this is not an easy undertaking.

McKinney and McNamara (1991) have indicated that, during ontogeny, contractions and extensions can occur at transitions between particular life-history stages and that local growth fields can also be modified. The reality that heterochrony may operate at any time during ontogeny (from the point of fertilization until the cessation of growth) has been blurred by the comparison of the cessation of a descendant’s growth with the ancestral condition (McNamara 1983; McKinney and McNamara 1991; Maier 1999). Mammals, for example, are characterized by embryonic and postembryonic (infantile, juvenile, adolescent, and adult) growth phases. In his thought experiments, McNamara (2002) (Figure 3.4) showed how some authors have described paedomorphosis where it was nonexistent. Sequential hypermorphosis (defined by him in 1983 as terminal hypermorphosis), for instance, also effects the offset of growth and therefore implicates greater development within each growth stage based on “scaling effects and probable increase in size, either of the part, or of the whole” (2002 p 108). Hence, the descendant is compared to the ancestor in a relatively more juvenile state. Paedomorphosis, however, should be defined by adult characteristics.

What kind of consequences does sequential heterochrony have for our understanding of human evolution? The list of “general neoteny—supporters” is long (I have already mentioned Bolk and Gould, but see also Montagu 1989; Wolpert 1991). Montagu’s (1989) favorite ancestor is a form very like the pygmy chimpanzee in order to compensate the incorrect assumption of Bolk that the hominid line has passed through an ape-like stage such as the gorilla–orang type. Provided that human is “essentially neotenous”, hominid evolution would have produced an organism characterized by having a smaller body size, brain, and limbs (Shea 1989; McKinney 1998). McNamara’s (2002 p 115) summary described hominid evolution as involving “a mixture of peramorphic and paedomorphic
McNamara’s (2002, © Johns Hopkins University Press) representation of the ontogeny of ancestral and descendant species that pass through distinct growth stages. (A–C at times T or T′). (a) A greater sequential hypermorphosis results in failure of the descendant to pass into stage C before cessation of growth at time T3. (b) Sequential hypermorphosis (Seq Hyp) at A and B results in the period spent in stage C being much shorter in the descendant. (c) Terminal hypermorphosis (Term Hyp) and sequential hypermorphosis result in all descendant growth stages being extended. (d) A shows an extreme sequential hypermorphosis and results in stage B being omitted in the descendant.
traits.” Forty years back, Starck and Kummer (1962) had come to a similar conclusion via a totally different method.

Shea (2002, p 95) applied his working hypothesis—size diversification occurs via predominant rate changes (rate hypomorphosis and hypermorphosis) rather than by time changes (time hypomorphosis and hypermorphosis)—to human evolution, and concluded that: “Certainly, at present no emergent data support any genetic or developmental basis for a global or generalized neoteny.” He accused Godfrey and Sutherland (1996) of revitalizing the idea that hominid evolution has predominantly involved a generalized neotenic transformation. This accusation is problematic in that Godfrey and Sutherland (1996 p 40) freely admitted that “Gould’s neoteny hypothesis for human evolution has been criticized on a number of grounds. The thesis of this paper is that both Gould and his critics overstated their cases: Nothing that we have said should be construed as a defense of Gould’s hypothesis. Our intention is simply to reopen the dialogue, and to propose a framework for more precise testing of heterochronic hypotheses” (My emphasis).

In contrast, Hall (2002 p 13) attacked the one-sided concentration on heterochrony as the only way to consider development and evolution by claiming that it “seemed that everyone could find evidence for heterochrony or at least justify use of the term to explain phenotypic changes in their favourite organism. Other mechanisms linking development and evolution were ignored or not sought.” He emphasized the importance of heterotopy, the spatial pendant of heterochrony.

In summary, I give below some important terms and definitions (see also earlier) based on Minugh-Purvis and McNamara’s (2002) summary, to present a brief synopsis:

<table>
<thead>
<tr>
<th>Term</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Acceleration</td>
<td>A heterochronic process that involves a faster rate of development in the descendant and also produces a peramorphic trait in the descendant</td>
</tr>
<tr>
<td>Deceleration</td>
<td>A slower rate of developmental events in the descendant. It produces a paedomorphic trait when expressed in the adult phenotype (syn. neoteny)</td>
</tr>
<tr>
<td>Hypermorphosis</td>
<td>Developmental events show a delayed cessation (or offset) in the descendant. Expressed in the adult phenotype, peramorphic traits are produced. Global hypermorphosis can be caused by late sexual maturation (terminal hypermorphosis). But hypermorphosis can also be caused by a delayed cessation in local growth fields</td>
</tr>
<tr>
<td>Isomorphosis</td>
<td>Peramorphosis followed by paedomorphosis (or vice versa). The descendant does not show any effective morphological changes. Unusual phenomenon of paedomorphosis</td>
</tr>
<tr>
<td>Neoteny</td>
<td>A slower rate of developmental events in the descendant, producing paedomorphic traits when expressed in the adult phenotype (syn. deceleration)</td>
</tr>
</tbody>
</table>
Paedomorphosis: The descendant adult retains subadult ancestral traits
Peramorphosis: The ancestral adult shows development of traits beyond the “usual” ancestral stage
Progenesis: Developmental events show an early cessation in the descendant. Expressed in the adult phenotype, peramorphosis is produced (syn. time hypomorphosis)
Sequential heterochrony: Contraction or prolongation in the descendant relative to the ancestor of life-history stages or ontogenetic growth
Sequential hypermorphosis: Life-history stages or ontogenetic growth are prolonged in the descendant relative to the ancestor (syn. proportional growth proportion)

3.3 Conclusions

Alberch (1982) rightly pointed to the importance of developmental constraints in evolutionary processes. It is nevertheless also important to emphasize the highly informative aspects of development (e.g. Britz and Bartsch 2003; Cracraft 2005; Alemseged et al. 2006; Brakefield 2006)—we should appreciate the synergistic effects. Considering paleoanthropology Dullemeijer (1975 p 86) predicted that “the fundamental idea can inspire many in their future research if the foetalization theory is reduced to the right proportions, ... It seems to open great perspectives for anthropology.” Two years later, Gould (1977) responded to this challenge and inspired a whole generation of biologists.

Most studies overwhelmingly reject a general neoteny phenomenon in human evolution. The conclusion of man’s domination by neoteny represents a pitheco-centric perspective: a fruitful, but wrong hypothesis. Sophisticated techniques, such as geometric morphometrics, and more embryological data indeed improve the quality of the data sets, but on the whole often verify traditional contributions. Gould’s (1977) brilliant forte, however, was primarily to break down the language barrier and to revitalize the topics of ontogeny and phylogeny. Summa summarum, I would like to conclude with Dullemeijer’s (1975 p 84) take-home message—not only in the figurative sense—by stating: “Homo sapiens has its own face.”

Acknowledgments

I am very grateful to Winfried Henke, Hartmut Rothe, and Ian Tattersall for inviting me to contribute. For intellectual support, I would like to thank Winfried Henke. Special thanks to Ian Tattersall for improving my pseudo-English manuscript, and I am very grateful to Jeffrey H. Schwartz for important comments. For inviting me to study Cynocephalus volans and for enriching discussions thanks to Wolfgang
Maier from the Institute of Systematic Zoology in Tübingen. Thanks also to Gerhard Storch, John R. Wible, Christian Kummer SJ, and Thorolf Hardt. The postgraduate financial support of the Johannes Gutenberg-University Mainz is gratefully acknowledged. Finally, Dankescho¨n to all my loved ones.

4 Principles of Taxonomy and Classification: Current Procedures for Naming and Classifying Organisms

Michael Ohl

Abstract

Taxonomy deals with the naming and classification of organisms and is an integrative part of biological systematics, the science of biodiversity. The information provided by taxonomic research is a fundamental basis for all fields of biology. Current taxonomy focuses on multicharacter integrative approaches, considering all potentially useful sources of information provided by the various fields of biology. The resulting supraspecific classification should be based on the genealogy of organisms, that is, on a phylogenetic analysis, to be objectively testable. However, for pragmatical reasons, a classification based on overall similarity and diagnostically relevant characters might be a heuristically important step in taxonomy and should be perceived as an approximation to a classification tested by phylogenetic methods. The nested levels in a classification of organisms are usually not only named but also ranked, that is, a set of hierarchical terms like genus, family, and class, are applied to reflect the hierarchical structure of the classification. Assigning these so-called Linnaean categories to a classification is (1) a voluntary action to make a classification notionally more easy to access; and (2) a linguistic activity that is done subsequent to obtaining the scientific results of the systematic analysis.

4.1 Introduction

Taxonomy, the science and method of naming organisms, is a fundamental basis for all biological science and its application. The primary task of taxonomy is to describe, establish, and give an account of the order that is an inherent property of biological diversity. The order of names provided by taxonomy is arranged as a hierarchical classification, which is considered to portray the hierarchy of species and more inclusive taxa as a result of the continuous chain of species splittings in
the evolutionary history of life on earth. Generalizations on organisms as a basic principle in biology are only possible if the infinite number of items in science is classified. Statements about the overwhelming diversity of nature would be impossible without methods for bringing order to this diversity. The world’s biota is a vast library of information concerning any aspect of life, and taxonomy is the cataloguing system that everybody must use to access its information. All kinds of biological science and applications link their specific data to species names and use these names for effective communication. As Longino (1993 p 85) has paraphrased, “… taxonomy is the raw material from which hypotheses of phylogeny are derived.” All kinds of comparative biology rely on sound phylogenetic hypotheses, and the reliability of a phylogenetic hypothesis immediately depends on the reliability of the underlying taxonomic data. Moreover, society has an increasing need for reliable taxonomic information in order to allow us to manage and understand the world’s biodiversity (Wheeler et al. 2004). Until recently, taxonomy was confronted with what Godfray (2002 p 17) called a new bioinformatics crisis, evidenced “by a lack of prestige and resources that is crippling the continuing cataloguing of biodiversity.” Current biological taxonomy quite successfully adopts methods, data structure, and other demands of techniques and theories invented by new entrants to the biological sciences such as the fields of molecular biology (e.g., DNA barcoding; see DeSalle et al. 2005). However, all other useful sources of information are simultaneously gathered in modern taxonomy, and this multicharacter integrative approach has been called integrative taxonomy (Dayrat 2005; Wheeler 2005). It allows taxonomists to create new common visions to meet changing demands of a changing global view on global biodiversity and the threats to it.

### 4.2 Definitions

Inconsistent terminology is a barrier to communication, results in confusion and misunderstanding, and prevents effective science. The variation in definitions for “taxonomy,” “systematics,” “classification,” and related or derived terms is as complex as it is contradictory. The major problem with these obviously closely allied terms is to differentiate them from each other, and many authors treat them more or less as synonyms, either intentionally or intuitively. In a recent textbook on biological systematics, Schuh (2000) implicitly equated systematics, classification, and taxonomy, when he defined systematics as “the science of biological classification.” The opposite view is held by Hawksworth and Bisby (1988 p 10), who suggested restricting taxonomy to “taxonomic information systems (classification, nomenclature, descriptions, identification aids)” and defining systematics
to include “taxonomy in the above restricted sense together with analyses of variation, of phylogeny, evolutionary processes, etc.”

Probably most current scientists would agree that the most appropriate name for the scientific area composed of taxonomy, systematics, classification, and all of their respective concepts, theories, and methods is “biological systematics,” or systematics in short.

What are the basic units of systematics? Systematics is not concerned with individual organisms, although these are always studied by systematists as representatives of species or other supraspecific groupings. The simplest and most descriptive statement would be that systematics deals with taxa. What then is a taxon (plural, taxa)? Simpson (1961 p 19) defined it as “a group of real organisms recognized as a formal unit at any level of a hierarchic classification.” This definition recognizes groups of organisms as taxa only if they are already formally classified, which is not always necessary or wanted. Newly discovered groups, hypothetical groups that still await confirmation, putatively artificial groups that are still disputed, and many others do not qualify as taxa under Simpson’s definition. In the field of phylogenetic systematics or cladistics, the taxon definition is often narrowed even further to monophyletic groups of organisms (Sudhaus and Rehfeld 1992; Mayr and Bock 2002). The final objective of systematics is indeed to include monophyletic groups only, but for a wide variety of reasons this goal can hardly be achieved right away. Hypotheses on monophyly are created and rejected, groups prove to be nonmonophyletic but are still being discussed, putatively monophyletic groups are still of unknown position within a certain higher lineage. Other problematic cases are fossil stem groups, like Australopithecinae, which are obviously paraphyletic with respect to Hominidae but can be treated as a heuristically important grouping in paleoanthropology. All these groupings are best referred to by a generalized term, and taxon is the most appropriate one. Hence, a definition of the term taxon might be: “A taxon is a group of organisms that can be differentiated from other groups of organisms, and that can be described and named.” Other terms to replace the term taxon have been proposed that are considered to carry specific connotations to reflect a specific framework for which they have been proposed. Terminal taxon, as used in cladistics, and operational taxonomic unit (OTU), proposed by the phenetic school of systematics, are two prominent examples that have been suggested to designate the units of systematics without reference to a particular rank or phylogenetic position. However, the term taxon, as here defined, is sufficient to refer to ranked and unranked groups of organisms.

Biological systematics in fact deals with taxa, that is, biological populations, species, and higher taxa. However, systematics is concerned not only with the taxa
themselves, their description and characterization but also with their origin, development, and other kinds of interrelationships. The fundamental and underlying concept of systematics is evolution, and Huxley (1940a, b) regarded systematics as “detecting evolution at work.” Simpson’s (1961 p 7) classical definition of biological systematics (or just systematics) is still adequate: “Systematics is the scientific study of kinds and diversity of organisms and of any and all relationships among them.” This definition was subsequently simplified to include the modern term “biodiversity,” e.g., Mayr and Ashlock (1991) and Sudhaus and Rehfeld (1992 p 11): “Systematics is the science of the diversity of organisms.”

Another term that plays an important role in biodiversity research is taxonomy. Taxonomy is not easy to differentiate from systematics, and it has been frequently intermingled with systematics. If separated, taxonomy usually refers to what Hawksworth and Bisby (1988 p 10) called “taxonomic information systems,” i.e., naming of taxa, nomenclature, descriptions, identification aids, whereas systematics is widely understood in a general sense of including taxonomy and the analysis of phylogenetic relationships, speciation processes, variation, and others. Since under any definition the terms taxonomy and systematics are closely associated, many authors have simply synonymized them because they consider their separation not to be feasible. The development of a concise methodology and theory of phylogenetic systematics in the last decades has considerably influenced the practice of modern taxonomy. Taxonomy, as understood here, might be treated as a field of systematics, with specific methods, theories, conventions, and terminologies that are different from other systematic fields (Will and Rubinoff 2004). There is, of course, continuous, active transgression of the borders between taxonomy and other branches of systematics, such as phylogeny and biogeography, and the most desired taxonomic revisions are obviously those whose taxonomic decisions are tested by phylogenetic analysis. To summarize, an appropriate definition of taxonomy might be (modified from Winston, 1999 p 9):

- Taxonomy is the branch of biological systematics that is concerned with naming of organisms (according to a set of rules developed for the process), identification (referring specimens to previously named taxa), and classification (ordering taxa into an encaptic hierarchy based on perceived characters).

The set of rules that governs the formation and use of taxon names in zoology is provided by the International Code of Zoological Nomenclature (hereafter referred to as the Code), published by the International Commission on Zoological Nomenclature and currently in its fourth edition. The Code and its bearing on taxonomy will be briefly discussed later. The definition described earlier points out that a classification of organisms is based on perceived characters. Any organism consists of innumerable numbers of characters that can potentially
be perceived by a biologist, but not all of them qualify as characters helpful in achieving a meaningful classification. The so-called phylogenetic systematics provides the objective framework for evaluating characters according to their meaning for the evolution of a taxon. The most reliable and testable classification is based on the results of a phylogenetic analysis, which tries to reconstruct the hierarchical structure of organisms as a result of the continuous sequence of speciation events in evolution. This should be the basic goal of all taxonomy. However, for different reasons, phylogenetic relatedness might (still) be unknown, and thus the set of perceived characters for establishing a sound classification might be selected inter subjectively by means of overall similarity and diagnostically relevant characters. A classification based on overall similarity might be a heuristically important step in biological systematics and should be perceived as an approximation to a classification based on phylogenetic hypotheses. In practice, such non- (or pre)phylogenetic classifications might stand for a long time, but they should be regarded as preliminary until tested by phylogenetic methods.

The previously mentioned definition of taxonomy implies that one of its main goals is a classification. As paraphrased by Schuh (2000 p 15), a “classification represents the codification of the results of [bio]systematic studies.” A general definition of classification might be

- A classification is a set of names that are ordered hierarchically and more and more inclusive. The hierarchy of names is considered to portray the hierarchy of organisms as the result of the evolutionary process.

Again, the hierarchy of organisms should preferably be recovered by means of phylogenetic methods, but might be preliminarily but meaningfully approached by the criterion of overall similarity.

Some authors (Griffiths 1974; Wägele 2005) differentiate classification from systematization for fundamental reasons. The term classification originates from the term class as in use in the philosophical logic and means a group of objects that have a specific set of properties in common. Which property is selected as class-defining is purely subjective and arbitrary, and a classification based on this property is similarly subjective. Thus a classification, as defined by Wägele and others, is considered to be a strictly conceptual system and is the product of an arbitrary, linguistic activity. In contrast, organisms are the product of the historical process of evolution, which is expressed as a continuous chain of speciation events during the history of life. The sequence of species splittings over millions of years has resulted in a hierarchical structure of the organisms that systematists achieve to reconstruct. Thus, this kind of hierarchy is conceptual as well, but it is considered to represent the hypothetically real sequence of speciation events in evolution. This process is called systematization by Wägele (2005).
The conceptual representation of the mental order as achieved by the process of systematization is called a phylogenetic system. The difference between a classification and a systematization is of fundamental importance but is usually not considered in practical biological systematics. I use the term classification for both ordering systems here, which is in accord with the widely accepted understanding, but we must keep in mind the resulting double meaning of classification and the respective subtle differences to systematization.

A completed classification is a hierarchy of names that denote hypotheses on taxa. It is organized in a more and more inclusive terminological structure of a theoretically infinite number of levels. These levels may bear names, but many of them, particularly in fully resolved cladograms with vast numbers of levels, remain unnamed for practical reasons. After completing a classification and selecting an appropriate number of higher taxa to be named, the hierarchically organized set of named levels can be given relative ranks as individual designations. Such relative ranks are provided by categories, such as classes, families, and genera, and this system of categories is well known as the Linnaean hierarchy or the Linnaean categories. Although the meaning and the current status of the Linnaean categories will be discussed later in more detail, it should be stressed here that an assignment of Linnaean categories to the level of a classification is (1) a voluntary action in order to make a classification notionally more easy to access; and (2) a linguistic activity that is done subsequent to obtaining the scientific results of the systematic analysis.

As we have seen previously, names as linguistic elements are of crucial importance in biological systematics. Names serve as labels to relate to concepts and hypotheses about taxa and their evolution. Names should principally be unequivocal, universal, international, and perpetual. Due to the incommensurably large number of organisms on earth, not to speak of the immense numbers of theoretically possible higher taxa that all could, at least in principle, be named, the need for internationally binding regulations is obvious. The part of taxonomy that is concerned with assigning names to taxa is called nomenclature. The sets of regulations that govern the practical application of nomenclature are provided by the International Code of Zoological Nomenclature.

### 4.3 Taxonomy as a system of ordering data

Biologists deal with a remarkable diversity of items. For any scientific procedure in biology, it is of critical importance to differentiate and thus to compare these items. It is one of the intrinsic attributes of a comparative process to arrange the to-be-compared items according to specified properties, that is, to classify these
items. Mayr (1995) differentiated four different kinds of classifications: (1) special purpose classifications (based on particular features of special importance in the context; e.g., ecologists may divide small mammals into soil-dwellers and tree-dwellers); (2) downward classification by logical division (starting with the entire animal kingdom, groups are defined on the basis of dichotomous splittings in two less inclusive groups, such as the warm-blooded and the cold-blooded animals, until the species level is reached); (3) upward or grouping classification (items are arranged in more and more inclusive groups according to observed characters); and finally (4) Hennigian phylogenetic or cladistic system (grouping of species and higher taxa on the basis of common descent). With respect to their nature as ordering systems, the upward classification (3) and phylogenetic systematics (4) do not differ, because in both classifications species are combined into higher taxa (ranked as genera), these higher taxa are combined into even more inclusive taxa, and so forth. However, phylogenetic systematics is a special kind of upward classification in permitting only one criterion as the basis for the classification, that is, common descent.

Five basic objectives of ordering systems can be differentiated in general and apply to biological systematics as well (Vane-Wright 2001; Mayr and Bock 2002): (1) discrimination (delimiting groups against other groups); (2) information storage and retrieval (the structure of classification systems, based on different criteria that are considered to be informative regarding the group, permits storage and retrieval of a large amount of information); (3) recognizing group affiliations (this is called identification and refers to the process of referring an organism to a previously described taxon, e.g., by the use of a dichotomous key); (4) inferences about not yet studied properties (it is a widely held prediction that many of the characters of a taxon studied will be similar or even identical to those of closely or immediately related taxa); (5) to serve as a baseline in comparative studies (the validity of comparative studies in biology largely depends on the reliability of the preceding research by which the studied items were grouped). These are basic objectives of that part of biological systematics that focuses on the biological items themselves, i.e., organisms, species, and higher taxa. The scientific treatment of these items requires a scientific terminology to communicate, which is provided by biological nomenclature.

4.4 Taxonomy and classification without phylogeny: an outdated remnant or a practical necessity?

There is an increasing shift in taxonomy toward modifying the directives on how to name organisms to reflect genealogical relationships. However, despite the fact
that most systematists would agree that the hierarchical system of names in biology should be governed by phylogenetic hypotheses instead of by intuitive similarity, the increasing pressure of phylogenetic demands on the naming processes results in intrinsic conflicts in systematics. Phylogenetic analyses have not been conducted for most groups of organisms yet, and it is highly unlikely that many will be undertaken soon. Additionally, new species are rapidly discovered in large numbers, particularly among invertebrates. Since a taxonomic treatment of such new taxa, that is, formal descriptions in taxonomic revisions or even single taxon descriptions, is a prerequisite to any other scientific exploration, new taxa are more rapidly described and made available than phylogenetic hypothesis are worked out. The taxonomic treatment of certain taxa, such as those that are less known, newly discovered, and or extraordinarily species rich, is a fundamental first step that opens up the possibility of continuing with subsequent phylogenetical, genetical, behavioral, and other studies.

In practical taxonomy, it is often necessary or at least recommendable initially to leave a comprehensive revision or a phylogenetic reconstruction aside from research projects and the resulting publications. In principle I agree with Mayr and Ashlock (1991 p 347) that “the isolated description of . . . new species . . ., divorced from revisional or monographic work, is the least desirable form of taxonomic publication.” But Mayr and Ashlock correctly qualify their assertion themselves in stating that it does not hold “in well-known groups.” A well-known group is usually a taxon which is not only well known in terms of scientific research but also which additionally receives extraordinary attention by both the scientific and the general public. It is thus not surprising that isolated descriptions of fossil and recent Primates and large mammals often make their way to the highest ranked scientific journals (e.g., the description of *Homo floresiensis* by Brown et al. 2004). Obviously, the publicity that results from such publications can be a strong motivation for any scientist to publish a rather isolated description immediately rather than to invest more time to obtain more data for a more comprehensive publication, due to the current system of scientists being under considerable pressure to publish and to compete for limited research money and, finally, jobs.

There are several more potential reasons to conduct descriptive taxonomy (Godfray 2002), which may mutually affect each other in most cases. Examples are: (1) it might be desirable to make a new discovery formally available for further studies, which can or should not be conducted at the time of discovery of the new taxon for varying reasons; (2) if a scientist has discovered a new species, and if he intends to describe it formally, this scientist might want to guarantee that the name of this taxon as proposed by him is the first formal description and, thus, has priority over any subsequent name. This might be considered as to
imply a connotation of personal rather than true scientific motivation, similar to the argumentation as presented earlier. However, priority is a basic principle of zoological nomenclature, and although it is explicitly thought to be priority of publication without reference to the date of discovery, the publication date here serves as an objectifyable reference point. Hence, priority of publication just replaces the priority of discovery for practical reasons; (3) incomplete knowledge of data might prevent systematists for conducting a comprehensive revision or a cladistic analysis. This might be due to the lack of characters (e.g., in fossils or other incompletely preserved specimens) or material (e.g., modern techniques such as molecular systematics or scanning electron microscopy require fresh or specifically preserved material, but many rare but potentially informative species are known only from dry museum material, which cannot be fully examined).

Another topic concerns the role of biological systematics in the context of a global biodiversity assessment. The development of global species inventories is considered to be an urgent and vitally important task that is a primary step and fundamental activity for any kind of biodiversity research (Stork and Samways 1995; Purvis and Hector 2000; Wilson 2003). Although it seems to be clearly unrealistic to describe every species of organism on earth, not to speak of the monumental uncertainties as to how many species there are (Godfray 2002), any step toward a global inventory of selected “target taxa” should be achieved as soon as possible.

Phylogenies are inherently hypothetical, simply because they portray historical processes, which cannot be inferred directly. Hypotheses, however, can be of different quality. The reliability of a hypothesis largely depends on the quality of the underlying data, which involves numerous theoretical and methodological aspects. Among these aspects, the completeness of the data set is of crucial importance. Completeness of characters is an illusion, since each single organism theoretically consists of an infinite number of characters. Completeness of taxa is, at least in principle, possible. With regard to taxon sampling, the perfect systematic study would include all species of a given taxon, perhaps even both still-living and extant. Practically, completeness of taxa is unlikely to be achieved in most groups, except perhaps for some exceptionally well-studied taxa such as birds. However, the reliability of a phylogenetic analysis increases with the increasing completeness of the taxon sampling. Conversely, gaps in the taxon coverage result in considerably less reliable phylogenetic hypotheses. In many cases, phylogenetic analysis should better wait for a more complete species inventory, which, particularly in taxa with many species or with a patchy distribution, can hardly be achieved in one step.

In summary, publications concerned with the taxonomy of a given group are most desirable if their classificational results are based on a comprehensive
phylogenetic hypothesis. If at all possible, a systematist should try to interpret his
taxonomic data with respect to the corresponding phylogeny rather than relying
on an intuitive character evaluation as a basis for a classification. Incidentally,
since the hierarchical structure of the organisms on earth is the result of a histori-
cally real, continuous sequence of species splittings, the hierarchy of organisms
as reconstructed by phylogenetic methods is in the end the only objective base for
a classification.

4.5 Zoological nomenclature: governing the
process of naming

Biologists are considered with a myriad items, and these items need to be named
to communicate concepts and hypothesis about these items in the biological
sciences. It is not only the millions of species that have to be named. The
hierarchical structure of the biodiversity of species and the myriad supraspecific
taxa result in an almost infinite number of items that in principle can be named.
Since names should be unequivocal in an international perspective, the formation
and practical handling of names of species and higher taxa obviously needs
internationally binding regulations. Nomenclature is the part of taxonomy that
regulates how names are assigned to taxa, and the underlying set of formal rules
of how nomenclature is applied in practical zoology is the International Code of
Zoological Nomenclature.

4.5.1 Ranking hierarchies: capacity and limits of
Linnaean categories

The Linnaean categories are terms that identify the hierarchical level in a classifi-
cation. Examples for categories are genus, family, and class. A limited number
of such categories date back to Carolus Linnaeus’ publications in the eighteenth
century, but the number of categories has increased continuously over time, the
better to reflect increasingly complex classifications. The rise of phylogenetic
methods in the last few decades has resulted in an increasing number of clado-
grams that depict complex, not directly linear relationships with a seemingly
infinite number of potential levels. It is, thus, not surprising that systematists face
a myriad practical problems when assigning Linnaean categories to classifications
based on cladograms resulting from phylogenetic analysis. Even in earlier phylo-
genetic publications, such as Hennig (1969), the conflicts between phylogenetic
results and categories were well known, and in that publication, Hennig replaced
the Linnaean categories by a system of consecutive numbers that directly reflects sister group relationships. However, his system received little attention from the beginning, because in less inclusive taxa, single numbers could be confusingly long (such as 2.2.2.2..4.6..1.1. Trichoptera, the sister group of 2.2.2.2..4.6..1.2. Lepidoptera). Hennig’s system seems to have disappeared from consideration.

Since that time, various nomenclatural systems have been proposed to eliminate or replace the Linnaean categories, one of the most recent and popular alternative concepts being the PhyloCode. It is beyond the scope of this chapter to present the characteristics, the advantages, and the failures of the PhyloCode, but I will focus on a critical assessment of the capacity and the limits of Linnaean system instead. It is still the most popular and widely accepted system of taxonomic ranking, and I will argue that this is not due to the uncritical persistence of antiquated principles but, conversely, for good reasons. The reader should consult one of the numerous papers on the Linnaean categories and their alternatives for more information, such as Cantino and de Queiroz (2002) in the World Wide Web, and Pleijel and Rouse (2003) in favor of the PhyloCode, and the rebuttals of arguments for the PhyloCode and its underlying theories by Nixon and Carpenter (2000, 2003), Carpenter (2003), Schuh (2003), and literature cited therein.

Ranking is an inherent property of any hierarchy in biological systematics, whether it is portrayed in a cladogram or by a formal Linnaean ranking scheme. Since ranking is included in any hierarchy, several unambiguous statements can be made concerning the structure of this hierarchy: for example, if taxon A is more inclusive than taxon B and actually includes B, then B does not contain A. However, the taxon names A and B themselves do not carry any reference per se about their relative position in the hierarchy, that is, whether A includes B, or vice versa, or whether A and B are of equal rank. In complex hierarchies, such as the hierarchy of organisms, the user is concerned with an overwhelming number of taxon names of different relative ranks, and he would be lost if any taxon bore an arbitrary name. Instead, communication is considerably more efficient if the ranking information is stated in addition to the taxon name. The Linnaean categories were invented exactly to convey this information by the use of standardized suffixes (for family-group names) and binominal nomenclature for species. As an example, the Cercopithecidae, the Old World monkeys, is usually ranked as a family (indicated by the suffix -idae) and, among others, contains the subfamily Colobinae (with the suffix -inae).

The Linnaean ranking system was, and still is, extremely successful, and this is partly because it is easy to understand and to learn. Alternative concepts that have been proposed to replace the Linnaean categories are explicitly rankless. Taxon names still exist, but they do not communicate any information at all
about their position in the hierarchy. The user can only understand the hierarchical structure by referring to the underlying cladogram. Hence, discarding Linnaean ranks and the binominal nomenclature results unnecessarily in the complete loss of important information on the taxa. This is not to say that the application of the Linnaean system is always unambiguous. Instead, there are numerous problems involved in taxonomic practice, particularly when portraying complex cladograms in a hierarchical classification. However, it seems unlikely that “[any] single system of nomenclature can ever possess all desirable attributes” (Schuh 2003 p 60).

4.5.1.1 Taxa and categories are not the same

There is a fundamental difference between a taxon and a category. As defined earlier, taxa are groups of real organisms that can be described and named. They can be monophyletic, nonmonophyletic, or phylogenetically untested. In contrast, categories are terms that can be assigned to taxa to connote a certain rank relative to other, more inclusive or less inclusive taxa. Taxa are the objects of biological systematics, whereas categories are a voluntary, notional tool that improves communication among systematists.

4.5.1.2 Categories and age

Linnean categories contain explicit and helpful information about the relative position of a taxon within a certain lineage. The central question in taxonomic practice is when we have a hierarchy of names that is supposed to reflect a hypothesis of relatedness (or at least overall similarity), how do we know which of the various levels should be ranked as an order or a family? To be honest, we actually never know, at least not precisely. The “alignment” of the hierarchy of taxa and the hierarchy of categories is determined by practical considerations, which is in the end a matter of subjectivity. However, there is a long lasting discussion of how to “objectify” the assignment of categories to a specific level in a classification. Actually, all efforts to do this have failed, and future efforts will probably fail. The reasons are easy to understand. Categories, as indicators of relative rank within a phylogenetic lineage of organisms, are inherently subjective, at least in a sense. It is a matter of usefulness for verbal communication and of convention and consistency, if, for example, taxon X is ranked as an order or a class. However, neither the hypothetically real hierarchy of organisms nor the categories themselves provide objective criteria how to applicate them.
However, several approaches to objectify categories have been published. Since phylogenetical reconstruction achieves to reconstruct historical events in the evolution of organisms, it is tempting to try to objectify the assignment of categories to taxa by using age as a criterion. This was already proposed by Hennig (1950, 1966), who discussed the problem of *absolute ranking* of higher taxa in exhaustive details. He suggested that the fossil record allows us to unambiguously define categories by the age of taxa to be classified. His example is the higher-level relationships of insects. Insects are generally considered to be ranked as a class, and since the oldest fossil insects, which belong in the Collembola, have been recorded from the Middle Devonian, the Collembola and their immediate relatives, which must have also been present at that time, would be assigned to what Hennig called a “class stage.” This resulted in the following ranking for Collembola: class Insecta, subclass Entognatha, infraclass Ellipura, microclass Collembola. Hennig, of course, realized that this approach is impracticable and arbitrary. He suggested to “reserve the well-known category designations (‘class’ and ‘subclass’) for the most important and morphologically isolated groups” (Hennig 1966 p 185), which can hardly serve an objective criterion. Hennig and subsequent workers were well aware that the age criterion of the categories across organisms or at least animals cannot work, simply because the major evolutionary radiations and subsequent diversifications took place in extremely different periods of time. As an example, the major lineages of the placental mammals that are generally ranked as orders arose in the Cretaceous (Murphy et al. 2001), and thus are comparable in age to the major lineages of Hymenoptera (bees, wasps, and ants), which are considered to be of family rank (Rasnitsyn 2002). If categories could be defined horizontally, the categorical hierarchies of Placentalia and Hymenoptera would have to be adjusted to each other, either by “downgrading” Placentalia to family rank or by upgrading Hymenoptera to class rank. This example clearly shows that a horizontal, *absolute* definition of the Linnaean categories is not only impractical but actually absurd.

However, a *vertical*, relative application of Linnaean categories along a phyletic lineage is a different matter and may be possible as a kind of evidence-based convention. An example is Goodman’s et al. (1998) cladistic analysis of the Primates based on DNA evidence and on extant and fossil morphological characters. Many traditionally recognized taxa appeared to be monophyletic, and their names and ranks as used in current literature were maintained. The ages of these clades were determined using dating evidence as provided by fossils and the model of local molecular clocks. Based on this time scale, clades of roughly equivalent age were assigned the same Linnaean rank. Goodman et al. (1998) analysis resulted in the following dating scheme (category/age [Mio years]/ geological period): semiorders/63/early Paleocene; suborders/58–50/late Paleocene to
early Eocene; infraorders/45–40/middle Eocene; superfamilies/39–29/middle Eocene to middle Oligocene; families/28–25/middle to late Oligocene; subfamilies/23–22/early Miocene; tribes/20–14/early to middle Eocene; subtribes/14–10/middle to late Miocene; genera/11–7/late Miocene; subgenera/6–4/late Miocene to early Pliocene.

It needs to be emphasized that an age-related Linnaean ranking might have merits only if applied to clades like the Primates with particular prerequisites. Primates have a widely accepted classificational framework (though the details are still disputed), quite a good fossil record, and cladistic analyses have been published with reliable taxon sampling. If the last common ancestor of the Primates is supposed to be as old as about 63 Mio years, and if the scientific community agrees to rank the Primate clade as an order, the highest level of the classification within Primates is defined: clades that arose in the early Paleocene are ranked as orders. Other, younger, fossils can be correlated with a particular rank accordingly. The fossil record, which might include gaps without fossil evidence, is supplemented by the model of the molecular clock, as proposed for Primates. This procedure allows applying the age criterion to any ranking level between the oldest reference point (the putative age of the last common ancestor of the Primates) and the youngest reference points (e.g., the latest splittings to clades generally ranked as subgenera, the youngest fossils).

Approaches like this pretend to be objective in correlating taxa and ranks, at least within the clade they were proposed for. However, it is easy to see that none of the criteria that define the age–rank correlation as proposed by Goodman et al. (1998) leads to an objectively settled ranking. It is a matter of convention if the clade named Primates, which is defined by a set of apomorphies and whose age of origin is defined by a particular fossil, is ranked as an order. Likewise, it is a matter of convention which of the clades within Primates, such as Cercopithecoidea, is assigned superfamily or any other rank. The same arbitrariness applies to the correlation of a clade and an age per se: with respect to the current state-of-the-art in Primate classification it might be useful to treat the putatively 18-Mio-years-old Cercopithecoidea as a superfamily, but other rank–age combinations might be similarly appropriate if suggested by the total hierarchy within Primates.

Nomenclatural stability is another important issue to be addressed to any classification concept. Stability of nomenclature should minimize changes in the names as they are adopted to changing scientific concepts. Age-defined ranks are, at any hierarchical level, extremely sensitive to the accuracy of the underlying dating of the latest common ancestors. New dating evidence, such as newly discovered fossils or new analytical methods in paleontology or molecular biology, may suggest fundamentally different dates of the origin of particular groups.
If, for example, the origin of Primates dates back to 80 Mio years as suggested by Tavaré et al. (2002), the age-related ranking scheme of Goodman et al. (1998) would have to be adopted to the new dating by stretching the ranking range to fit to the longer period of time or by adding more category levels.

The standard approach to calibrating a classification for an age-related application of ranks is to use the earliest known fossils of a particular taxon and to equate their age with the time of origin of this taxon. The resulting age of the taxon under discussion is, obviously, hypothetical and only gives us the so-called “terminus post quem non,” that is, the point of time after which the clade cannot have originated. In other words, the fossil record only settles the minimum age of the group. This can potentially lead to a serious underestimate of the true time of origin of a clade, and hence, of all other dating results inferred secondarily. As has been pointed out by Martin (2002), this underestimation increases if the fossil record is very patchy. Since this might be the case in many organisms (Tavaré et al. 2002), the oldest fossil of a given clade might be considerably younger than its true stem species. As a result, age-defined ranking schemes are considerably different depending on whether the dating as inferred directly from the fossil evidence, or the dating as indirectly estimated by molecular clock models or estimations of extinction rates and the reliability of the fossil record, is considered.

These applications and problems show that an age-defined, objective correlation of Linnaean categories and clades is as unrealistic, if not impossible, as any other effort toward an absolute definition of ranks. In some cases, such as Primates, age-defined ranks may be useful to some extent, although it must be emphasized that the correlation of ranks and clades even in such cases is at most intersubjective, being based on a set of conventions of the respective scientific community. Changing conventions, changing dating evidence, and other factors may considerably alter the putatively objective ranking of Primates. The Linnaean categories are a notional representation of the hierarchical structure of monophyletic taxa representing an inferred, hypothetical sequence of speciation events (or, if a cladistic analysis is still lacking, an a priori assumption of relatedness inferred from overall similarity). As a consequence, the Linnaean system is inherently relative, that is, Linnaean ranks denote the hierarchical position of a given taxon relative to other members of the same clade. As has been paraphrased by Schuh (2003 p 60), “[t]he primary strength of the Linnaean system is its ability to portray hierarchical relationships.” It must, however, be emphasized that Linnaean categories are inherently subjective in that the exact correlation of a taxon and its rank are not determined by the taxon or the category themselves.
4.5.1.3 Ranking fossils

Fossil and recent taxa are basically treated in an identical way in taxonomy. However, if fossils are included in a cladogram, a number of practical terminological problems arise. Fossils are part of the stem lineage of a given taxon, and each single fossil taxon is considered the sister group of the next, less inclusive, taxon. If sister taxa are given the same rank in the hierarchy, each single fossil species that is considered to be the sister species of a taxon that is ranked as an order must be assigned order rank as well. If several fossil species of a given stem lineage in a continuous sequence of sister group relationships with the next less inclusive taxon are known, each of these single species would have to be given a high rank, which would, for example, result in a proliferation of taxa ranked as orders along a single lineage. In principle, each of the pairs comprising a fossil species and its higher sister taxon could also be assigned a new name.

As a consequence, giving a high rank to each of the fossil species would not only appear to be overblown, but this would also ignore the fact that the exact sequence of fossils along a stem lineage cannot be determined accurately in most cases. As an alternative, Patterson and Rosen (1977) have suggested to order fossils according to their hypothetical phylogenetic position but to leave them unranked. Instead, each of these fossils is named *plesion*. The term *plesion* replaces any rank above the genus level and to tentatively place fossils in cladograms without affecting the hierarchical structure of names and their ranks.

4.5.1.4 Linnaean categories as a communication tool

Systematists should be aware that the Linnaean categories are a tool for communication. As Griffiths (1976 p 168) stated, there is no logical reason why taxa *must* be ordered into categories. Linnean categories do not inherently imply information about the age of a taxon (except if employed within a certain clade by convention, as e.g., in Primates), the size of a taxon (in terms of species numbers), genetic distinctiveness, or phylogenetic relatedness. The application of a particular rank to a particular taxon is subjective but must fit in the overall hierarchy of the more inclusive taxa.

But Linnean categories directly mirror the complex, hierarchical relationships in a given clade. Along this lineage, the nestedly ordered categories notionally reflect the nested order of organisms and explicate the relative position of a given taxon to other taxa of the same lineage. The demand for an abolition of the Linnean categories without substitution involves well-known practical problems and would result in the loss of practical and useful information. There is a
myriad practical problems involved in the implementation of the Linnaean categories, but this is also the case in any other notional system of ranking. “No single system of nomenclature can ever possess all desirable attributes: i.e., convey information on hierarchical relationships, provide ... stability in the names . . ., and provide simplicity and continuity in communicating the identities of the taxa and their relationships” (Schuh 2003 p 60). Since the discussion about the Linnaean categories reflects the problems how best to express scientific contents linguistically, applicability is the central criterion to assess the capability of any ranking concept. The search for the “best” biological nomenclature corresponds to the search for compromise between theoretical demands and practical necessities.

4.5.2 The International Code of Zoological Nomenclature

Systematists and, secondly, subsequent users of the results of biological systematics, deal with a myriad objects: each taxon, if considered a species or ranked as a genus, family, or order, can be recognized as a biological entity, which, to a varying degree, is distinctly different from other such objects. To enable communication about this objects, in principle requires the application of unique names, which unequivocally refer to the taxa. Even in pre-Linnaean times, the need to point to groups of organisms by names was obvious. However, before Linnaeus, the names given to taxa were thought to be descriptive or diagnostic terms or phrases rather than proper names, as we see taxon names today. Although easily recognizable organisms might have been given single names (uninomina) or, if two closely related forms were known, two-word (binominal) names were coined. Increasing knowledge of the diversity of forms made complex, descriptive labels necessary to meet the criterion of uniqueness (e.g., the gentian species that is today known as *Gentiana ciliata* was named *Gentiana angustifolia autumnalis, minor floribus ad latera pilosis* by Bauhin (1623) (Mägdefrau 1992); note that Bauhin and other pre-Linnaean authors already employed unique genus names as more inclusive taxa). Linnaeus, however, introduced a strictly formal nomenclatural system, based on a unique binominal species name. The increasing exploration of remote geographic regions made scientists realize that they are concerned with a seemingly infinite organismic diversity. Due to new discoveries and new techniques taxon names proliferated. However, it was not only the increase in species descriptions that lead to a rapid increase in the total number of taxon names. Inconsistent or even contradictory terminological systems, development of their own rules by many scientists, replacement of already published names that were considered to be inappropriate or incorrectly
formed, and other factors, resulted in the strong need for general rules of nomenclature.

Beginning with Linnaeus’ works in the eighteenth century, an elaborate body of conventional regulations was developed to provide such general rules. The valid rules of nomenclature in zoology are contained in a judicial text called the International Code of Zoological Nomenclature, here abbreviated as the Code, whose current edition is the fourth. The Code provides a complex set of rules and aims to cover as much of the complexity of the recent and historical naming process as possible. However, cases might show up in which the strict application of the Code might actually threaten nomenclatural stability, and in such cases every scientist is free to apply to the International Commission of Zoological Nomenclature to set aside priority or other provisions of the Code to increase stability. Many provisions of the Code are the result of compromise between conflicting principles, which partly date back to the very beginning of biological nomenclature. Hence, the rules fixed by the Code are far from written in stone but are under constant development. As has been emphatically pinpointed by Mayr and Ashlock (1991 p 386), “all good law is living law.”

An exhaustive description of the Code is far beyond the scope of this chapter, but a few basic principles will be considered here.

4.5.2.1 Freedom of taxonomic thought

The Code does not tell anybody how to classify something or how to recognize species or other taxa. These are scientific decisions that are totally under the responsibility of the systematist. The Code provides rules for a system of communication, a “language,” for communicating such taxonomic decisions. This “freedom of scientific thought” is expressly guaranteed in the Preamble of the Code, and, indirectly, emphasizes the role of nomenclature in biology as a notional process acting subsequent to the scientific process. As an example, the Code permits a scientist to continue using a name that is considered to be a junior synonym by another author. Conversely, the freedom of taxonomic thought includes also the freedom to make taxonomic mistakes that, as a consequence, do not affect nomenclature. If, for example, a name is erroneously placed in synonymy, its validity is not affected.

4.5.2.2 New names and old names

The process of naming a newly discovered species properly, that is, in accord with the Code, is surprisingly simple. The Code explicitly provides a set of provisions
to be met when describing a species, some of which appear to be commonsense principles. To be usable or, to use the proper term, to be available, a name must, first, be published. The Codes clearly indicate that distribution “in numerous identical copies . . . for permanent record” constitutes a publication. The use of the 26 letters of the Latin alphabet for the taxon name is mandatory, although the descriptive text may also be written using a different alphabet. A name must, of course, in principle be unique but on different levels: a species name must only be unique in its own genus (there are several animal species with popular species names like viridis, meaning green, but no two species (or subspecies) in a genus may bear this name), whereas a genus name must be unique among all animals. However, it is wise to avoid species names that are already in use in closely related genera. In the future, genera might be combined due to changing evidence, which would result in homonymy of such species names. A new species name “must be explicitly indicated as intentionally new,” that is, by adding a Latin term like “new species” to the newly proposed name or an equivalent phrase or abbreviation. The Code also requires the consistent application of binominal nomenclature, which does not apply to names of taxa at ranks above the family group). A new species description must also include an explicit fixation of the name-bearing type specimen(s). A type is an individual specimen to which a given name is attached. In cases in which a taxon previously considered a single species is later split into two species, the species to which the type specimen belongs retains the previously given name. This type method is important in taxonomy and will be presented in more detail later. Finally, the Code provides a set of mandatory regulations of more linguistic nature, how new names are to be formed. The most important provision is that names must be either Latin or latinized or they must be so constructed that they can be treated as Latin words. Further rules concern practical details such as how names are formed from personal names and other aspects of the correct spelling.

Every scientist who plans to propose a new name for a taxon should consider these simple provisions to be sure that the new name complies with the Code. However, the greater part of the Code is devoted to less simple cases, and most of the problems are caused by names proposed in the past. A smaller part of difficulties systematists face when dealing with previously published names might be caused by the erroneous application of the Code or by erroneous taxonomic decisions. The majority of problems, however, simply portray the continuously changing concepts and applications in the 250-year-old history of biological systematics. Such changes might affect scientific content (e.g., by the invention of alternative species concepts) or might be more formal (e.g., the explicit designation of a name-bearing type was not mandatory at the beginning of biological systematics). As a result, historical names are not only hard to locate
in the literature in many cases, they often require time-consuming, elaborate efforts to clarify the correct original spelling, the presence of type material, the identity of the species, the correct date of publication of the original description, and several other potential difficulties. Two of the most common problems that come up when dealing with historical names are synonymy and homonymy.

The fact that a considerable portion of taxonomic practice is unusually time consuming when compared to the outcome, i.e., the clarification of a single species name, is part of the legacy of about 250 years of biological systematics. In many groups of organisms, taxonomists are condemned to spend most of their time interpreting the work of pre-twentieth-century systematists. “The past [often] acts as a dead weight on the subject, the complex synonymy and scattered type material deterring anyone from attempting a modern revision” (Godfray 2002 p 17).

4.5.2.3 Validity, synonymy, and homonymy

As I have explained earlier, a taxon name must fulfill a set of conditions to be available in terms of Code compliance. Among the available names, only the oldest available name is what systematists call valid and has priority over the younger names. The valid name of a taxon is sometimes referred to as the correct name, which means that open nomenclatural problems have been solved and that a single name retained, that under the provisions of the Code, is the only approved one. The date of publication of the original description of a name is thus of crucial importance and must be carefully determined. It must be emphasized that the principle of priority applies to the species, genus, and family levels only but not to levels above the family rank.

In by far the most cases the valid name is the oldest name. Exceptions occur when the oldest name, in case of a species, is already in use in the genus, resulting in homonymy. Then the younger of the homonymous names would no longer be valid but must be replaced by the next available name of the same species, if any exists. An example is a subspecies of the common Chimpanzee, Pan troglodytes verus Schwarz, 1934 (originally described as a subspecies of Pan satyrus Linnaeus, 1758, the species name of which was suppressed by the International Commission on Zoological Nomenclature in 1999). The oldest available name of this subspecies is Simia chimpanse Matschie, 1904, but, despite having priority due to the early publication date, Matschie’s name cannot be used because it is a junior homonym of another species, Satyrus chimpanse Mayer, 1856. Since Satyrus chimpanse Mayer is considered to be identical to, that is, a synonym of, the
nominate subspecies, *Pan troglodytes troglodytes*, the species group name *chimp-\textit{anse* occurs twice within *Pan*, by Matschie, 1904, and by Mayer, 1856, respectively. This is called *secondary homonymy*, since the two names under discussion were first proposed in different genera and got in conflict after being considered to belong in the same genus. *Simia chimpanse* Matschie was published half a century later than *Satyrus chimpanse* Mayer, and thus as the younger of the two names must be replaced. The next available name is *Pan satyrus verus* Schwarz, published in 1934, which then becomes valid. In many species, however, no name is available other than the originally proposed name. Then the revising author has the authority to propose a replacement name, which then becomes available with the reviser as the correct author and the date of his publication.

If a single taxon is given two or more names, each of these names is a *synonym*. The earliest published synonym is referred to as the *senior synonym*, even if it is considered to be the valid name. Any other earlier names of the same taxon are called *junior synonyms*. In most cases in practical taxonomy, systematists are confronted with the question if two independently published species names that were based on different name-bearing types actually represent the same species. This kind of synonymy with different types is called *subjective synonymy* because it expresses the scientific conviction of the revising author that the two names refer to the same thing. Names applied to a species on the basis of the same type specimens are *objective synonyms*.

### 4.5.2.4 Typification: establishing objective reference points

The type method is a guiding principle in biological systematics. In taxonomic practice the identity of species, particularly when described in the past, is often difficult to establish due to insufficient descriptions or illustrations. As a result, historical species descriptions might apply to more than one currently recognized species. Due to new evidence, taxa might be split up into two or more less inclusive taxa. In all such cases, it might be difficult to establish which of the newly separated taxa has to retain the original name and which should be newly named. This problem is solved by the invention of objective reference points, the types. Types in the broadest sense are zoological objects to which a name is firmly tied. The type of a species is always a single specimen, the type of a taxon at genus rank is a species, and finally, the type of a family-rank taxon is a genus. If a previously described species is considered to be actually composed of more than one species, the type specimen fixes the original name to the species, to which it belongs. The same holds for taxa at the genus and family ranks.
The Code permits the use of a few different kinds of types in taxonomic descriptions. At the genus and the family level only type species and type genera exist, respectively. A **holotype** is always a single specimen, which is either the only specimen available for the original description, or it is explicitly selected out of the original series of more than one specimen to give it precedence over the other specimens, which then are called **paratypes**. In current species descriptions, the explicit designation of a holotype is mandatory. Paratypes do not have special standing under the Code but should be explicitly mentioned as members of the original type series by calling them paratypes. If the original describer in older publications mentions more than one specimen but did not select a holotype, all type specimens are the **syntypes**. A syntype series is of little help in conflicting taxonomic situations because they might actually belong to more than one species. In such cases, a revising author has the authority to subsequently select a single specimen from the original type series, which then would be called a **lectotype**. Accordingly, the remaining syntypes would be the **paralectotypes**, which, again, are only of secondary importance. If the type material of a species is considered to be lost, the revising author may select a specimen that was not part of the original type series, as a **neotype**. In some cases, the lack of type material is of minor importance because the identity of the species is obvious. An example is *Homo sapiens* Linnaeus, 1758, for which no type specimen or specimens have ever been settled (Spamer 1999). A neotype must be designated only if this action facilitates nomenclatural stability so that the name is properly and consistently applied. Since a neotype is required in cases with unsettled and problematic nomenclature, one can almost never be completely sure if the neotype and the original type are really conspecific. Thus, designation of a neotype might be risky and should only be done if absolutely necessary. Numerous other kinds of types have been used in the literature, but only those above are still permitted under the current Code. Examples of types that are not regulated by the Code are allotypes (a specimen of the opposite sex of the holotype, actually simply a paratype) or toptype (a specimen originating from the type locality of the species to which it is thought to belong).

Incidentally, it is a widely held belief that the type specimen or specimens of a newly described species must be dead or should be killed sooner or later to be finally deposited in a museum collection or in another kind of persisting and accessible environment. This means that in most cases a new species description is based on one or more specimens that are physically available to the scientist during the process of writing the description. The Code requires that the specimen (the holotype) or specimens (syntypes) on which the name is based must be explicitly stated and accompanied by description or diagnosis to differentiate the new taxon. However, this requirement does not include any mandatory
provisions about the physical availability, detailed morphological description, or depository of the type specimen (Wakeham-Dawson et al. 2002).

A type specimen need not be especially typical for the species to which it belongs. Its function is simply that of a “name bearer” (Simpson 1961). There are several potential criteria for how to select a holotype out of the entire material that is available to a scientist. If the species is differentiated from its congeners by means of complex morphological features of the male genitalia (as is common in invertebrates), it might be appropriate to make a male the holotype. Sometimes not all type specimens are complete or show the diagnostic characters equally well. It would make sense to choose as the holotype a specimen, which exhibits most or all of the characters that are of diagnostic value at the time of description and with respect to new future discoveries as far as can be predicted.

The description of a new species is always based on all specimens available at the time of description. Since the holotype is just a name bearer, its function is not to serve as the only basis of the original description (except when only a single type specimen is known).

### 4.5.2.5 Fossils, fragments, and heterogeneous type specimens

The Code applies to both living and extinct animals, as is explicitly stated in its Article 1. Thus, the principles of the type method as briefly presented earlier with reference to recent species are equally applicable in paleontology. However, many fossils, particularly complex multistructured organisms, such as vertebrates, inherently lead to practical problems. In most fossil vertebrates, only hard structures are fossilized and thus preserved. In the course of diagenetic processes, soft tissues that connected the hard elements in the living animal are usually decayed so that the resulting skeleton falls apart. In the ideal case, the preserved elements remain in their original position after embedding in a fossilization matrix so that the elements can easily associated with each other. In many cases, subsequent physical processes might have altered the relative position of the elements or have destroyed parts of the organism.

Fossil hominids are never completely preserved, not even with respect to bones. Sometimes just a single preserved bone is sufficient to provide evidence for taxonomic identity. If a single bone is the basis of a new taxon, just the bone is referred to as the holotype. An example is the holotype of *Homo heidelbergensis* Schoetensack, 1908, which consists of a complete, adult mandible. There is no ambiguity about the formal basis on which the new species is based. If more than a single element is available, association to individual can be difficult if the elements are not in the original position relative to each other but are more or
less dislocated or destroyed. An example is the composition of the types of *Homo habilis* Leakey, Tobias, and Napier, 1964. Several fragments assignable to the new species were available such as mandibles, isolated teeth, parietals and hand bones, and cranial fragments. Due to external evidence, such as the position of the fragments as found during excavation, the fragments could be associated with five individuals. The holotype of *H. habilis* consists of a mandible with dentition and the associated upper molar, parietals and hand bones, originating from a single juvenile individual.

These examples show another principle of the type method. A type is always a zoological object but is not necessarily something that is or is close to a complete organism. A single tooth, an isolated wing, or any other part of an organism is in principle sufficient to serve as the basis for a new species. In a way incompleteness is an inherent attribute of most preserved specimens because many preservation techniques result in the loss of some characters. Pinned, that is, dried insects and stuffed, mounted vertebrates have usually lost all or most of their soft tissue. Thus, even if a specimen has lost almost the entire physical structure except for a single tooth, this incompleteness of a specimen does not prevent potential type status. It is, however, wise to associate isolated fragments such as a molar and a mandible to a single type specimen only if the evidence is unambiguous. If subsequent evidence is found that the fragments actually belong to different individuals, this might cause a lot of unnecessary nomenclatural confusion.

5 Quantitative Approaches to Phylogenetics

Kaila E. Folinsbee · David C. Evans · Jörg Fröbisch · Linda A. Tsuji · Daniel R. Brooks

Abstract

We review Hennigian, maximum likelihood, and different Bayesian approaches to quantitative phylogenetic analysis and discuss their strengths and weaknesses. We also discuss various protocols for assessing the relative robustness of one’s results. Hennigian approaches are justified by the Darwinian concepts of phylogenetic conservatism and the cohesion of homologies, embodied in Hennig’s Auxiliary Principle, and applied using outgroup comparisons. They use parsimony as an epistemological tool. Maximum likelihood and Bayesian likelihood approaches are based on an ontological use of parsimony, choosing the simplest model possible to explain the data. All methods identify the same core of unambiguous data in any given data set, producing highly similar results. Disagreements most often stem from insufficient numbers of unambiguous characters in one or more of the data types. Appeals to Popperian philosophy cannot justify any kind of phylogenetic analysis, because they argue from effect to cause rather than cause to effect. Nor can any approach be justified by statistical consistency, because all may be consistent or inconsistent depending on the data being analyzed. If analyses based on different types of data or using different methods of phylogeny reconstruction, or some combination of both, do not produce the same results, more data are needed.

5.1 Introduction

Formalized by Willi Hennig in 1950, phylogenetic systematics has emerged as a universal and transparent method for generating and evaluating phylogenetic hypotheses. Over the last 50 years, it has developed into a research program ostensibly embraced by a majority of evolutionary biologists who are interested in exploring the patterns and processes of evolution. However, this apparent unity is misleading. As researchers from diverse fields began putting the theory and methods into practice, they approached their studies from different perspectives.
and using different types of data. This has generated a multitude of quantitative methods and research strategies, the efficiency and validity of which are fiercely debated in the literature.

These debates stem partly, perhaps largely, from the nature of phylogeny reconstruction. Unlike much of physics and chemistry (astronomy and astrophysics being notable exceptions), in which experiments in a hypothetico-deductive framework aim to be predictive with respect to spatiotemporally invariant laws, the reconstruction of phylogenies deals with a singular history and thus is descriptive and retrodictive. Attempts to infer causal processes for evolutionary patterns must be based not only on evolutionary patterns of relationships but also on corroboration from independent data (Brooks and McLennan 2002). Despite these obstacles, evolutionary biologists strive to provide as accurate an approximation of evolutionary history as possible.

Paleoanthropologists, like all paleontologists, should be especially concerned with the accurate reconstruction of primate evolution, partially because fossils provide some of the most powerful evidence supporting evolution, the unifying theory of biology. More particularly, paleoanthropologists are the curators of information about the most fascinating evolutionary story of all, the story of Us. As a critical part of evolutionary biology, paleoanthropology thus stands to benefit enormously from participation in phylogenetic research programs. Collaborating with researchers in diverse fields and exploring new methods will allow paleoanthropologists to refine their hypotheses and methods while placing them within the larger context of biotic evolution on this planet.

5.2 Fount of stability and confusion: A synopsis of parsimony in systematics

The principle of parsimony (Latin parcere, to spare) is also known as the principle of simplicity. The principle is often connected to the English philosopher and Franciscan monk William of Ockham (ca. 1285–1349), who advocated the use of the principle so forcefully that it is also known as “Ockham’s razor”: Pluralitas non est ponenda sine necessitate (plurality should not be posited without necessity) and non sunt multiplicanda entia praeter necessitatem (entities should not be multiplied unnecessarily). In this sense, the principle represents an epistemological tool or rule of thumb, which obliges us to favor theories or hypotheses that make the fewest unwarranted, or ad hoc, assumptions about the data from which they are derived. This does not necessarily imply that nature itself is parsimonious. Aristotle (350 BCE) articulated an ontological basis for the principle of parsimony, the postulate that “nature operates in the shortest way possible”
and “the more limited, if adequate, is always preferable” (Charlesworth 1956). This sense of the principle postulates that nature is itself parsimonious in some manner. Phylogeneticists have used the term “parsimony” in both senses, resulting in much confusion and, from our perspective, unnecessary conflict.

The most important concept introduced by Hennig (1950, 1966) was the stipulation that we should assume homology in the absence of contradictory evidence. Although now known as Hennig’s Auxiliary Principle, this concept lies at the foundation of evolutionary theory. “[p]erhaps the correct way of viewing the whole subject, would be, to look at the inheritance of every character whatever as the rule, and noninheritance as the anomaly” (Darwin 1859 p 13), and “Mr. Waterhouse has remarked that, when a member belonging to one group of animals exhibits an affinity to a quite distinct group, this affinity in most cases is general and not special” (Darwin 1872 p 409). Hennig’s argumentation method is clearly intended to maximize hypotheses of homology and minimize hypotheses of homoplasy, which invokes the principle of parsimony by avoiding the assumption of unnecessary ad hoc hypotheses of parallelism. In the Hennigian system, if evolution were parsimonious, all traits would be logically consistent with the true phylogeny—there would be no conflicting relationships suggested by any set of traits, that is, there would be no homoplasy. The Auxiliary Principle implies that there will be conflicts in the data, which should be resolved in favor of the hypothesis postulating the fewest number of assumptions of multiple origins (homoplasy) over single origins (homology). Contemporary Hennigians assert that both the Auxiliary Principle and the use of parsimony are logical requirements of any attempt to reconstruct phylogeny; if one were to assert that all similarities were due to homoplasy, there would be no evidence of common descent, and thus no evidence of evolution. Therefore, if one is going to study evolution, one must use a method that is capable of finding evidence of evolution. Likewise, if one is going to invoke the Auxiliary Principle, one must invoke it for all traits, thereby choosing the phylogenetic hypothesis that minimizes the total number of violations of the Auxiliary Principle for a given set of data. In this manner, the Auxiliary Principle is an epistemological tool practically synonymous with the principle of parsimony (Farris 1983; Wiley et al. 1991). Wiley (1981) suggested four main assumption of phylogenetics: (1) evolution occurs and has occurred, documented by the characters of different species; (2) each species is a historically unique mosaic of plesiomorphic, synapomorphic, and autapomorphic traits; (3) before the analysis we do not have knowledge about which characters are homologous and homoplasious; and (4) we do not know beforehand what the phylogenetic relationships are, nor do we know the relative or absolute rates of divergence. The presumption of homology embodied in Hennig’s Auxiliary Principle is not an a priori assumption in the sense of a formal
model, because the method is designed in part to recognize all mistakenly presumed homologies as homoplasies.

Edwards and Cavalli-Sforza (1963, 1964) reconstructed a tree of extant human populations based on frequencies of blood-group alleles, using an approach they developed and called the “Method of Minimum Evolution.” Their studies originally aimed to present a maximum likelihood method for phylogeny reconstruction, but their algorithm for a likelihood approach did not work. Edwards (1996 p 83) later emphasized that “[t]he idea of the method of minimum evolution arose solely from a desire to approximate the maximum likelihood solution,” that is, from a maximum likelihood model based on the assumption that evolution has been parsimonious. Felsenstein (2004 p 127) characterized the method of minimum evolution as a parsimony method, while at the same time not seeing a direct connection between Hennig’s Auxiliary Principle and the principle of parsimony, e.g., “[i]t is not obvious how to get from this ‘auxiliary principle’ to the parsimony criterion” (Felsenstein 2004 p 138). This reveals that for Felsenstein and like-minded phylogeneticists, parsimony is an ontological issue, whereas Hennigians see it as an epistemological issue.

There are two critical distinctions between these positions. The ontological perspective on parsimony requires first that evolution be parsimonious in some manner, usually as defined by certain assumptions and parameters of a model; and second, that the resulting phylogenetic hypothesis be accepted as true so long as the model is accepted as true. Practitioners are thus preoccupied with the accuracy of their results, and believe it is possible to develop means by which their preferred hypotheses can be verified with respect to the true phylogeny. The Hennigian or epistemological use of parsimony does not imply that the evolutionary process itself is parsimonious. In fact, it suggests that evolution has been so complex that we should always expect to find conflicts in the data, which will require the use of a logical decision-making principle to resolve. An important corollary of this perspective is that there need be no necessary connection between the most parsimonious hypothesis and truth. Practitioners are thus preoccupied with the empirical robustness of their results. The expectation is that if the most parsimonious hypothesis is not true, the accumulation of additional data will force phylogeneticists to abandon it in favor of a new most parsimonious hypothesis; they do not believe that their hypotheses can be verified, but do believe that they can use new data to falsify all or parts of previous hypotheses. Phylogeny reconstruction is thus an open-ended process involving a potentially endless search for information. If, at some point in the future, the accumulation of data has led to a situation in which the phylogenetic hypothesis for a given group is no longer changing with the addition of new data, Hennigians
may express the belief that the hypothesis has approached the truth as closely as possible, but in principle it is never appropriate for a Hennigian to claim to have the true phylogeny. Hennigians do feel justified in claiming that they have the most robust hypothesis possible for any set of data.

Today numerous quantitative methods for reconstructing phylogenetic trees are applied to multiple kinds of characters. These methods can be divided into two main types, commonly called parsimony (invoking epistemological parsimony) and likelihood (invoking ontological parsimony) approaches.

5.3 Epistemological parsimony: The Wagner algorithm

In September 1965 two articles on phylogeny and parsimony appeared. Wilson (1965) introduced a “consistency test for phylogenies based on contemporaneous species.” His null hypothesis was that all characters that are used for a phylogenetic analysis are unique and unreversed. In order to pass Wilson’s consistency test, the taxa defined by these characters must be nested and these nested conditions must persist as new species are added to the tree. Colless (1966) was concerned that more than one cladogram might pass the consistency test, that a polyphyletic character state might mistakenly be regarded as unique and unreversed, and that the taxa are in the first place grouped on the basis of similarities. Wilson (1967 p 104) asserted that his consistency test was internally sound, but that he shared one of Colless’ main concerns, which “is the lack of efficient methods for selecting the character states.”

That concern was discussed in the second article published in 1965 in which Camin and Sokal (1965) presented the first algorithm for applying the parsimony criterion to phylogenetics and first applied the term “parsimony” to a method of phylogenetic inference. They used a group of imaginary animals (Caminalcules) possessing a number of morphological characters that could change according to particular rules. Thus, the “true phylogenetic tree” was known and could be compared to trees that were achieved by different methodologies. Camin and Sokal (1965) found that the trees that most closely resembled the “true phylogeny” required the least number of changes in the morphological characters, which seems to invoke an epistemological use of parsimony. However, they claimed that their technique examined “the possibility of reconstructing cladistics by the principle of evolutionary parsimony” (p 312), saying that “the correctness of our approach depends on the assumption that nature is, indeed, parsimonious” (pp 323–324), an appeal to ontological parsimony. Significantly, Camin and Sokal produced a computer program implementing their method, demonstrating for the first time that quantitative phylogenetic analysis could be performed on as
objective a basis as phenetics, thereby undermining one of the strongest arguments in favor of phenetics over evolutionary approaches to systematics (Sokal and Sneath 1963). Their algorithm was unwieldy and inefficient for larger data sets, and was never fully adopted nor effectively programmed and made available for widespread use.

Soon afterward, Kluge and Farris (1969; also Farris 1970) presented a new algorithm for reconstructing phylogenetic trees as well as searching among several trees for the most parsimonious tree for a given data set. They named their method “Wagner parsimony” in honor of W.H. Wagner, who formalized an older approach (Mitchell 1901, 1905; Tillyard 1921; Sporne 1949, 1953; Danser 1950) called the groundplan-divergence method (Wagner 1952, 1961, 1969, 1980), which formed the basis for Kluge and Farris’ algorithm. Kluge and Farris (1969) also discussed explicitly their perspective that the use of the parsimony criterion did not assume that evolution itself is parsimonious, clearly invoking an epistemological use of the principle.

5.3.1 The Wagner algorithm

Kluge and Farris’ (1969) method minimizes the Manhattan distance between members of a set of taxa via the creation of hypothetical taxonomic units. The first Wagner algorithm (in later papers termed the “simple Wagner algorithm”) is constructed as follows:

**Definition:** \( X(A, i); \) state = \( X_i \), of character \( i \), for Taxon A

\[ D(A, B) = \sum_i [X(A, i) - X(B, i)] \] (1)

\( D(A, INT(B)) \) is the difference between A and interval B;

\[ D(A, INT(B)) = \frac{D(A, B) + D(A, ANC(B)) - D(B, ANC(B))}{2} \] (2)

Step 1. Choose an ancestral taxon.
Step 2. Find the operational taxonomic unit (OTU) that is the least distance from the ancestor, using Eq. 1. Connect the taxon to the ancestor, forming an interval.
Step 3. Find the next taxon that is next least distant from the ancestor.
Step 4. Find the interval from which the taxon found in step 3 differs least, using Eq. 2.
Step 5. Attach the taxon found in step 3 to the interval found in step 4 by constructing an intermediate (hypothetical ancestor), Y, and insert it into the
tree at this interval. The character states of Y will be the median of the three nodes surrounding this newly created intermediate.

Step 6. If any taxa remain unplaced, go to step 3, otherwise stop.

Example:

Using the same four-taxon, five-character statement as was used in the groundplan-divergence example (Table 5.1)

Table 5.1
Exemplar of a four-taxon, five-character statement

<table>
<thead>
<tr>
<th></th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>
</tr>
</thead>
<tbody>
<tr>
<td>K</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>L</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>M</td>
<td>1</td>
<td>1</td>
<td>0</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>N</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>1</td>
<td>0</td>
</tr>
</tbody>
</table>

Step 1. As in the example for groundplan-divergence, K is determined to be the ancestor.

Step 2. Requires us to find the difference between the ancestor (or outgroup) and each of the other taxa using equation 1.

\[
D(L, K) = \sum_i [X(L, i) - X(K, i)] \\
= [1 - 0] + [0 - 0] + [0 + 0] + [0 + 0] + [0 + 0] \\
= 1
\]

So the difference between L and ancestor K is 1. We must then determine the difference between the ancestor (K), and each of the other taxa in the matrix, using the same equation.

\[
D(M, K) = 3 \\
D(N, K) = 4
\]

We find that the difference between L and K is the least, so we connect L to K via an internode, as shown below. This interval will be known as interval L (INT (L)) (Figure 5.1):

Step 3. The next step is to determine which taxon to add to the cladogram next. It is the one that is the next closest (least different) from ancestor K. In this case, it happens to be taxon M (with a difference of 3 from above).

Step 4. To figure out the interval to which we can add M, we must calculate the distance between M and each of the intervals on the diagram. At this point, there
is only one interval so it is self-evident to which interval the taxon will be added, but the calculation is:

\[
D(M, \text{INT}(L)) = \frac{D(M, L) + D(M, \text{ANC}(L)) - D(L, \text{ANC}(L))}{2}
\]

\[
= \frac{2 + 3 - 1}{2}
\]

\[
= 2
\]

Step 5. Taxon M is then added to INT(L) via a hypothetical intermediate, Y (Figure 5.2).

Hypothetical intermediate Y is given the character states that are the medians of those taxa to which it is connected (L, M, and K). It is then added to the character matrix as in Table 5.2:

Step 6. The next taxon to be added to the diagram is the last remaining one, N. We now must determine the interval to which we must add N. To do this, we find the difference between N and each of the intervals. INT(M), INT(L), and INT(Y) using equation 2.
\[ D(N, \text{INT}(M)) = 2 \]
\[ D(N, \text{INT}(L)) = 2.5 \]
\[ D(N, \text{INT}(Y)) = 3 \]

N is found to differ least from \text{INT}(M), so it is added to that interval via a hypothetical intermediate, X, whose character states are the median of M, N, and Y. The network is now complete (Figure 5.3).

Farris (1970) concluded that it was unnecessary to have an ancestor from which to begin the construction of the tree. He observed that the choice of ancestor of a given group of taxa changed the topology of the tree. Since the “simple” algorithm did not impose directionality to the evolution of the group, he reasoned that the choice of ancestor is not crucial. Since parsimony assumes the least about the way evolution works, then choosing one taxon as an ancestor would be assumption about the status of that taxon. He thus argued that a rootless network would reduce the dependency of the form of the tree on the

\begin{table}[h]

ancestor. For the creation of networks, he used a method for creating networks that minimized the length of the intervals between taxa (symbolized by nodes), using the shortest network connections method of Prim (1957; Sokal and Sneath 1963). Farris differentiated his use of this method from previous phenetic applications by its use of shared, derived characters, and also by the evolutionary implications of the method. This new Wagner algorithm differed from that of the “simple Wagner algorithm” as follows:

1. Find the pair of OTU’s that differs the most (using equation 1 from above).
2. Compute the advancement index of each taxon from the interval formed between the two initial taxa.
3. Take the taxa with the largest advancement index and add it to the interval via an HTU.
4. Find the next unplaced OTU with the largest “advancement index,” find the interval from which it differs least.

This produces a network, rather than a tree, and does not assume that any of the taxa are ancestral. Farris suggested that the network could be converted into a phylogenetic tree by rooting it at one of the taxa within the tree, or an interval within the network. Completing the process of constructing phylogenies using this method requires that the characters be optimized onto the tree.

The earliest programs implementing the Wagner algorithm did not necessarily find the most parsimonious tree for large data sets. The program needed to run multiple times and have a method of comparison in order to determine whether it has indeed found the shortest tree, or if there were multiple equally parsimonious trees. In a large matrix, examining every possible tree could require an enormous amount of computer time, and thus it became necessary to develop heuristic methods to try to find the shortest tree. Today’s parsimony programs, such as those in PAUP, Hennig 86, and NONA, use a variety of heuristic algorithms to rerun the data to attempt to ensure that the most parsimonious tree or trees are found. For small numbers of taxa and characters, the Branch and Bound algorithm (Hendy and Penny 1982), which guarantees finding the shortest tree, or the Exhaustive Search option, which enumerates all possible trees, can be employed.

As phylogeneticists began to analyze increasingly larger and more complicated data sets, shortcomings in the original computer programs became evident. In the decade following Farris’ (1970) contribution, a number of algorithms were developed, such as Fitch parsimony (Fitch 1971) and Dollo parsimony (Farris 1977), which were incorporated into the existing programs as alternatives to Wagner parsimony. These differed primarily in their assumptions and restrictions regarding character evolution and are discussed in more detail by Wiley et al. (1991).
The first iteration of the Wagner algorithm did not take into account multistate characters, and therefore technically it was not possible to have unordered states, since polarized binary characters are automatically ordered. Initially, before more variations were developed for the algorithm, it was suggested that all multiple character states be divided into multiple binary characters [e.g., a single multistate transformation series of an imaginary character (absent (0), short (1), long (2)) would be divided into two separate characters (absent (0), present (1)) and (short (0), long (1))]. Current algorithms allow for multistate transformation series and allow characters to be run either polarized or unpolarized, and either ordered or unordered, at the discretion of the user. Again, the advantage of phylogenetic methodology is that these decisions are transparent (if they are reported) and repeatable; with the same data set, anyone can rerun an analysis using the same settings to check the reliability of the analysis, or change the settings to see if the results are different.

Whatever algorithm you use to build a tree, in most cases some characters will not be decisive at every node (Farris 1970). It is therefore important for the purpose of studying character evolution to be able to optimize characters on a tree. There are two types of optimization, ACCTRAN (Farris 1970; Wiley et al. 1991) and DELTRAN (Swofford and Maddison 1987; Wiley et al. 1991). The ACCTRAN setting accelerates the transformation of a character on a tree, pushing the evolution toward the root. This is equivalent to preferring parallelisms to reversals, if the choice does not affect the tree length. DELTRAN delays the transformation of a character on a tree, essentially choosing reversals over parallelisms when they are equally parsimonious (Wiley et al. 1991). When there are no equally parsimonious alternatives, both ACCTRAN and DELTRAN will provide the same result (Figures 5.4 and 5.5).

Figure 5.4
DELTRAN tree (length = 9 steps). Redrawn and modified from Wiley et al. (1991)
5.3.2 Development of outgroup comparison

As noted above, Wagner algorithm generates a minimum-length network (sometimes called an “unrooted tree”). In order to convert a Wagner network into a phylogenetic tree, the network must be rooted in some manner. Increasingly, published studies convert the network into a tree by rooting it with an arbitrarily chosen single taxon not included in the group being analyzed (called the ingroup). This protocol should not be mistaken for the method of outgroup comparisons that emerged in phylogenetics during the 1970s. The distinction is slight, but significant, and must be understood in light of Hennig’s perspective on the issue of ancestors.

Hennig objected strongly to the notion that phylogeny reconstruction could be achieved by reconstructing a series of archetypal ancestors, from which particular descendant species could be derived. His position was that each species was a unique mosaic of plesiomorphic and apomorphic traits. Archetypes, defined as ancestral species exhibiting only plesiomorphic traits, thus did not exist; therefore, no single taxon could be used to determine the plesiomorphic and apomorphic traits for any analysis. Or, using current jargon, rooting a network with a single outgroup taxon is sufficiently robust in the Hennigian system only if that taxon is the archetype ancestor of the ingroup, something the Hennigian system disavows.

As can be seen from the discussion above, the early development of the Wagner algorithm was not informed directly by Hennigian reasoning. Rather, it relied on the groundplan-divergence method, based on a priori recognition of an

![Diagram](attachment:image.png)
archetypal ancestor. When Farris (1970) abandoned the a priori reliance on an ancestor, the Wagner algorithm reverted to a method for producing an unrooted network. Lundberg (1972) made a significant contribution to linking the results of Wagner analyses with Hennigian analyses by differentiating ancestors from outgroups.

He developed a method to determine an ancestor from within a network from the data within that same network. He opined that the structure of a network makes certain character states more likely to be ancestral, helping to determine which interval should form the root of the tree of a parsimony-optimized network. The transition of emphasis from searching for ancestors to identifying outgroups was critical in linking Wagner with Hennig.

The idea that similarity in traits even among distantly related species was due to homology (i.e., plesiomorphy) rather than independent evolution (homoplasy) was established before the development of Hennigian systematics.

> ... it would in most cases be extremely rash to attribute to convergence a close and general similarity of structure in the modified descendants of widely distinct forms. The shape of a crystal is determined solely by the molecular forces and it is not surprising that dissimilar substances should sometimes assume the same form; but with organic beings we should bear in mind that the form of each depends on an infinitude of complex relations, namely on the variations that have arisen, these being due to causes far too intricate to be followed out,—on the nature of the variations that have been preserved or selected, and this depends on the surrounding physical conditions, and in a still higher degree on the surrounding organisms with which each being has come into competition,—and lastly, on inheritance (in itself a fluctuating element) from innumerable progenitors, all of which had their forms determined through equally complex relations. It is incredible that the descendants of two organisms, which had originally differed in a marked manner, should ever afterwards converge so closely as to lead to a near approach to identity throughout their whole organisation. If this had occurred, we should meet with the same form, independent of genetic connection, recurring in widely separated geological formations; and the balance of evidence is opposed to any such admission. Darwin (1872 pp 127–128)

Despite the fact that the connection between outgroups and the Auxiliary Principle had been around for a long time, there was no codification until the late 1970s. Engelmann and Wiley (1977) were the first to provide a rationale for outgroup comparisons. They pointed out that the reference to species outside the ingroup permits a researcher to distinguish traits that truly conflict with phylogeny (homoplasies) from those that only appear to conflict (plesiomorphies). This in turn creates the possibility that phylogenetic analysis could become testable, at
least with respect to Darwinian concepts. Watrous and Wheeler (1981) expanded on this idea, suggesting a number of rules to determine ancestral states for each independent character on the basis of comparisons with an outgroup taxon. The first algorithm to determine ingroup relationships with reference to multiple outgroups was presented by Maddison et al. (1984), who showed that the most robust outgroup comparisons relied on two or more paraphyletic outgroups. This algorithm is incorporated in the program PAUP to root networks when outgroups are specified.

Closely related to the issue of using outgroups to reconstruct ancestral character states are the terms and meanings of “global” and “local” parsimony, which were first applied by Maddison et al. (1984). They proposed a two-step procedure that measures parsimony locally among the outgroups to determine ancestral states and given that these ancestral states then measures locally within the ingroup. This results in one or multiple ingroup cladograms that are most parsimonious globally, i.e., most parsimonious in the context of related groups.

We previously addressed the connection between the Auxiliary Principle and epistemological parsimony. Linking the Auxiliary Principle to outgroup comparisons thus provides a connection, through the Auxiliary Principle, between outgroup comparisons and parsimony. It is the use of outgroups to root the shortest network that makes the Wagner algorithm Hennigian, accounting for high degrees of consistency between Wagner algorithm, groundplan-divergence method, and Hennig argumentation of the same data (Churchill et al. 1984).

5.4 Evaluating the robustness of a parsimony analysis

5.4.1 Character evaluation

As noted in the introduction, Hennigian phylogeneticists are preoccupied with assessing the empirical robustness of their results. There are various methods available to accomplish this goal. These “goodness of fit” measures are useful indicators of the degree of internal conflict among the data (characters) used. Measuring the robustness of the characters and knowing how they behave over the tree topology is one useful approach.

The simplest summary statistic is the tree length; it is merely the number of steps required to produce a particular topology, and it is calculated by adding the number of character changes over the tree (Wiley et al. 1991). Parsimony analysis chooses the tree, or trees with the shortest overall length, given a set of characters.

Consistency indices (Kluge and Farris 1969) attempt to quantify the amount of homoplasy on a particular tree. The original form of the consistency index (CI)
is the ratio of the total number of apomorphic states to the tree length. A high CI indicates there is little homoplasy (i.e., the tree length approaches the minimum number of steps required) and a low CI indicates there is a high degree of homoplasy. This measure is independent of a particular data set and thus can be used to compare trees produced by different data. However, the CI can be inflated by autapomorphies, which do not represent tests of relationships and thus are not informative with respect to the robustness of the tree. Farris (1989) therefore proposed the rescaled consistency index (RC). The RC is an adjusted version of the CI with the influence of characters that do not change the fit of the tree (e.g., autapomorphies) removed. It still gives a relative measure of the degree of homoplasy on a particular tree topology.

5.4.2 Tree evaluation

A second type of evaluation assesses the robustness of the tree topology itself. Decay analysis (Bremer 1988) determines the number of steps required to collapse nodes. To perform a decay analysis, we increase the tree length by successive steps. This shows how many trees exist that are one or more steps longer than the most parsimonious tree (MPT); if there are a number of trees of similar length to the MPT, but with different topologies, we might place less confidence in the MPT. A decay analysis will also reveal how many added steps it takes to collapse individual nodes, and which specific characters influence those nodes. This in turn allows us to test whether a set of functionally correlated characters influences a particular node. TreeRot (Sorenson 1999) is a computer program that uses PAUP* to perform decay analysis, although it is possible (albeit time consuming) to do it manually by successively adding one to the tree length in the search parameters.

Hennigian analysis of a data set may produce more than one tree with the same number of fewest possible steps, a phenomenon known as multiple most parsimonious trees. With a large number of taxa and characters, especially if they contain large amounts of homoplasy or missing data, parsimony frequently generates multiple MPTs. In these cases, it is not possible to designate a single preferred tree; however it is possible to generate a variety of consensus trees to delineate similarities in topologies of different MPTs (Adams 1972; Wilkinson 1994).

There are different techniques to build consensus trees that combine the topological information from two or more trees to create a new summary tree. Strict consensus trees only include monophyletic groups that appear in all of the input trees, and thus usually result in a number of polytomies (Sokal and Rohlf 1981).
Adams consensus trees are slightly more inclusive, purporting to give the most resolution between a set of trees (Adams 1972). These may, however, produce groupings not found in any of the input trees. Majority-rule consensus trees are perhaps the most lenient and frequently used summary tree technique (Margush and McMorris 1981). They are created by building a new tree that contains all monophyletic groups that are supported by a majority of the set of input trees. This means that they may be logically inconsistent with the information produced by one of the MPTs. Consensus techniques are useful as visual summaries of points of agreement or logical consistency between MPTs, but they are not phylogenies, and they are not equivalent to what is produced by phylogenetic analysis of a data matrix. Occasionally, the consensus tree will be one of the MPTs in which case it is a summary tree as well as a phylogeny. Usually, the creation of consensus trees results in the creation of a number of polytomies, or nodes in which the relationships between taxa are unresolved. These are known as soft polytomies when they are created by lack of resolution due to insufficient data or methods. Hard polytomies are actual speciation events, in which a population divides simultaneously into three or more descendent species, or in which two sister species hybridize, forming a third species (Brooks and McLennan 2002). These are impossible to distinguish from soft polytomies with a phylogeny alone.

Bootstrap and Jackknife analyses attempt to estimate the degree of sampling error in the original data set, by attempting to place confidence intervals on phylogenies by making inferences about the variability in the data set. Bootstrapping (Felsenstein 1985a) samples the data set with replacement, that is, it allows for some characters to be sampled more than once, and some not to be included at all and constructs a new data set with the same number of characters. PAUP* (Swofford 1998) and other programs construct a series of these, and build a majority-rules consensus tree that summarizes the results of the resampled data. The number of times a particular group is included in the set of trees that form the consensus is an estimate of the reality of that group, in that the process has measured the amount of variation between the newly sampled data sets. The bootstrap, then, is a measure of the confidence we can place in each node of the tree, like the decay index. Felsenstein (1985a) suggested that a bootstrap value of 95% or greater offers statistically significant support for a clade.

There are a number of caveats of which we must be aware before placing too much faith in the numbers generated by this analysis. Since the bootstrap measures the variation in one set of data, it does not allow us to choose between trees built from different data sets. Felsenstein (1985a) stipulated that a bootstrap assumes characters are independent and equally distributed. He was explicit that the bootstrap indicates repeatability of an analysis given the data, and should not
imply the phylogenetic accuracy of a tree (Soltis and Soltis 2003). It will also be affected by biases such as long-branch attraction (Swofford 1998).

The jackknife is another mode of evaluation, similar to the bootstrap in that it estimates variability in the data set. It is a procedure to resample data by deleting a certain number of characters [either half (Felsenstein 1985a) or another fraction (Farris et al. 1996)] and resampling the data without allowing characters to be duplicated. Characters are randomly and independently deleted from the original matrix to create a new “resampled” matrix, and like the bootstrap, many matrices are produced and the results are compiled into a consensus tree. For a review of the different kinds of jackknife resampling (delete-half, parsimony, weighted) and the assumptions and problems with each see Efron (1979), Wu (1986), and Farris et al. (1996).

5.5 Ontological Parsimony: Maximum likelihood and Bayesian likelihood

5.5.1 A precis of maximum likelihood in phylogenetics

Microbiology made significant progress in the late 1950s when the first proteins were sequenced. Molecular data were soon realized to be an important source of phylogenetic information useful in inferring evolutionary relationships (Sneath and Sokal 1973; Neyman 1974). Edwards and Cavalli-Sforza (1963, 1964) first explored the idea that likelihood could be applied to phylogeny reconstruction. Edwards and Cavalli-Sforza (1964; Cavalli-Sforza and Edwards 1967) later described a likelihood method for phylogenetic inference using blood-group allele frequency data in human populations. Neyman (1974) was the first to apply likelihood analysis to nucleotide sequences, and presciently suggested that this approach might become important in the future. Farris (1973) and Felsenstein (1973) published likelihood algorithms for phylogeny reconstruction, however problems of computational difficulties continued to limit a likelihood method for phylogenetic inference to the theoretical rather than practically operational. Felsenstein (1981b) introduced the first computationally efficient maximum likelihood algorithm for discrete character nucleotide sequence data. Just as the Wagner algorithm became the algorithm of choice for quantitative Hennigian analyses, nearly all phylogenetic applications of maximum likelihood are adapted from Felsenstein’s early work. Since then, maximum likelihood methods have become increasingly popular in phylogenetic studies (Swofford et al. 1996; Huelsenbeck and Crandall 1997; Tuffley and Steel 1997; Felsenstein 2004). These approaches are most commonly used in molecular phylogenetics (Swofford
et al. 1996; Huelsenbeck and Crandall 1997; Huelsenbeck et al. 2002; Ronquist 2004), but morphology-based and combined likelihood and Bayesian methods have been proposed and are being refined (Lewis 2001; Nylander et al. 2004; Ronquist 2004).

### 5.5.2 Likelihood methods

Several methods for inferring phylogenies from nucleotide sequence data are available, resulting in an often-heated debate among evolutionary biologists over the “best” way to approach phylogeny reconstruction (Goldman 1990; Penny et al. 1992; Swofford et al. 1996; Huelsenbeck and Crandall 1997; Steel and Penny 2000). Maximum likelihood methods evaluate a hypothesis of evolutionary relationships using a presumed model of the evolutionary process and evaluate the probability that it would give rise to the observed data, which is typically DNA sequences of the terminal taxa (Felsenstein 1973, 1981b, 2004; Swofford et al. 1996; Huelsenbeck and Crandall 1997). It should be noted that there are several different types of the likelihood (Steel and Penny 2000; Goloboff 2003). Phylogenetic-likelihood approaches use maximum average likelihood, a form of maximum relative likelihood (except Farris 1973, that adopted evolutionary pathway likelihood), and only this form applies to the discussion below (Steel and Penny 2000).

The likelihood of a hypothesis (Fisher 1922) is the probability, \( P \), of the data \( D \), given the hypothesis \( H \):

\[
L = P(D|H) \tag{3}
\]

The likelihood of a parameter is proportional to the probability of the data and it gives a function that usually, but not always, has a single maximum value, which Fisher called the maximum likelihood. The likelihood does not estimate the probability of the hypothesis, which is assumed to be true in the likelihood formulation (Eq. 3).

Likelihoods are calculated for possible tree topology, given the data and assuming a particular model of molecular evolution (Felsenstein 1973, 1981b, 2004; Swofford et al. 1996). In the likelihood equation, Eq. 3, the hypothesis, \( H \), contains three distinct parts: (1) a mechanism or model of sequence evolution, (2) a tree or a hypothesis of relationships, and (3) branch lengths (Penny et al. 1992). For a given data set, likelihoods are calculated for each of the possible tree topologies, or a sample of them, and the tree topology with the highest overall likelihood is the preferred phylogenetic hypothesis. The number of possible tree topologies increases with the number of terminal taxa included in the analysis.
This can be computationally laborious if the data set is large, and especially if the maximum likelihood model uses rooted trees in its calculus. However, the most general and most commonly used models in molecular analyses are time reversible (Rodriguez et al. 1990; Swofford et al. 1996). With a time reversible model the probability of character state change from state \( i \) to state \( j \) is the same as the probability of state change from state \( j \) to state \( I \) (Felsenstein 1981b). Under this condition the likelihood of the tree does not depend on the position of the root, and the use of unrooted networks greatly reduce the total number of trees to be evaluated, and decrease computation time (Rodriguez et al. 1990; Swofford et al. 1996). In a four-taxon statement, there are three possible unrooted networks (Figure 5.6):

![Figure 5.6](image)

**Figure 5.6**

</tbody>
</table>

For each network, likelihoods are evaluated on a site-by-site basis. The probabilities (\( P_{ef} \)) of all possible combinations of character states at the internal nodes are calculated for each site (i.e., each character) using a specified model of molecular evolution and estimated branch lengths (see below). The likelihood of the site is the sum total of all the probabilities for all the possible combinations of character states at the internal nodes of the network (Felsenstein 1981b; Swofford et al. 1996; Huelsenbeck and Crandall 1997). In the four-taxon case, there are two internal nodes and therefore 16 possible combinations of character states and 16...
probabilities for each site (when gaps are not considered) (Eq. 4). It is clear that some of these combinations, or scenarios, are more plausible than others given the data at the leaves. However, every combination of states at the internal nodes is theoretically possible and each is therefore given a probability (Figure 5.7).

\[ L_{\text{site}} = P_{AA} + P_{AC} + P_{AG} + P_{AA} + P_{CA} + \cdots \]  

(4)

</table>

The overall likelihood of the network or tree is calculated as the product of the site likelihoods \(L_{\text{site}}\) because each site is assumed to evolve independently of one another (Eq. 5).

\[ L_{\text{tr1}} = L_{\text{site1}} \times L_{\text{site2}} \times L_{\text{site3}} \times \cdots \times L_{\text{sitenn}} \]  

(5)

Theoretically, this procedure is repeated for each possible unrooted network, although there are “pruning” algorithms that do not require every tree to be considered thereby improving computational efficiency in large data sets (Felsenstein 1981b; Swofford et al. 1996). The network with the highest overall likelihood is the maximum likelihood result, and the preferred phylogenetic hypothesis. It is the network topology that maximizes the likelihood function for the data given the specified model (Felsenstein 1973). It is possible that the network represents only a local maximum, or that it is one of a larger number of equally likely networks. It is important to remember that the likelihood of a network is
NOT \( L = P(H|D) \), which is the probability of the hypothesis. The network is converted into a tree by rooting it with an outgroup or a molecular clock (Swofford et al. 1996; Felsenstein 2004).

### 5.5.3 Models of molecular evolution

Likelihood analyses involve similar assumptions about the evolutionary process as other methods, including that evolution occurs in a branching pattern and is independent in different lineages (Swofford et al. 1996). The probability of a particular combination of character states at the internal nodes of the unrooted network (e.g., Eq. 4.), are calculated using a specified model of molecular evolution, which requires further assumptions about the nucleotide substitution process, including that sequence evolution can be modeled as a random, or stochastic, process (Rodriguez et al. 1990). Substitution models are typically based on a homogeneous Markov process (Rodriguez et al. 1990; Swofford et al. 1996) that assume the probability of a state change at one site does not depend on the history of that site and that probabilities of substitution do not change significantly in different parts of the tree (Felsenstein 1981b, 2004; Swofford et al. 1996).

A DNA substitution model is expressed as a table of rates (substitutions per site per evolutionary distance unit) at which nucleotides are replaced by alternate nucleotides known as the Q matrix (Rodriguez et al. 1990; Swofford et al. 1996; Huelsenbeck and Crandall 1997). The term \( Q_{ij} \) in the instantaneous rate matrix, \( Q \), represents the rate of change from base \( i \) to base \( j \) over an infinitesimal evolutionary time period \( dt \) (Swofford et al. 1996). The Q matrix in Eq. 7 represents the general time reversible (GTR) model. Change probabilities are determined by the relative rate of change supported by the instantaneous rate matrix \( Q \) and estimated branch lengths.

\[
Q = \begin{bmatrix}
-\mu(a_{fC} + b_{fG} + c_{fT}) & \mu a_{fC} & \mu b_{fC} & \mu c_{fT} \\
\mu a_{fC} & -\mu(a_{fA} + b_{fG} + c_{fT}) & \mu b_{fG} & \mu c_{fT} \\
\mu b_{fA} & \mu a_{fC} & -\mu(b_{fA} + d_{fC} + f_{fT}) & \mu f_{fT} \\
\mu c_{fA} & \mu e_{fC} & \mu f_{fC} & -\mu(c_{fA} + e_{fC} + f_{fG})
\end{bmatrix}
\]

(6)

The rows and columns correspond to the bases A, C, G, and T. The mean instantaneous rate factor, \( \mu \), is modified by the relative rate parameters \( a, b, c, \ldots, f \). The relative rate parameters correspond to each possible base substitution scenario. The rate parameter is the product of \( \mu \) and the relative rate parameters. The remaining terms (\( f_A, f_C, f_G, f_T \)) represent the frequencies of the four bases.
The base frequency parameters, calculated over all taxa, are assumed to be at equilibrium and that the rate of change from one base to another is proportional to the equilibrium frequency (Rodriguez et al. 1990; Swofford et al. 1996).

The rates defined in the Q matrix are per instant of time $dt$, in order to calculate the likelihoods of each site, the probabilities $(P_{ij})$ of the possible state changes along a branch length of $t$ (Swofford et al. 1996) must be determined. A substitution probability matrix (sensu Swofford et al. 1996) is calculated using Eq. 7:

$$P(t) = e^{Qt}$$

Calculation of the exponential is complex, involving the decomposition of the Q matrix into is eigenvectors and eigenvalues (see Swofford et al. 1996 for references). For the simple Jukes–Cantor model, these values are relatively easily evaluated because there are only two probabilities, the probability of a state change and the probability of stasis, such that the transition probability matrix consists of two values, as in Eq. 8:

$$P_{ij}(t) = \begin{cases} 0.25 + 0.75 e^{-\mu t} (i = j) \\ 0.25 - 0.25 e^{-\mu t} (i \neq j) \end{cases}$$

The substitution probability matrix that corresponds to the GRT instantaneous rate matrix Q in Eq. 7 similarly has 12 values, 1 for each of the different substitution rates. The branch lengths are unknown prior to the analysis and must be estimated in the course of the likelihood calculation (Goloboff 2003). Estimation of branch lengths involves an iterative algorithm in which each branch is optimized separately (Felsenstein 1981b; Swofford et al. 1996). Unlike the rate and frequency parameters, branch lengths are specific to a particular tree topology. For each tree, multiple different branch lengths need to be evaluated, and branch lengths must be recalculated for each unrooted tree considered (Penny et al. 1992).

Models employed in likelihood analyses make explicit assumptions regarding sequence evolution, the number of which depends on the particular model of sequence evolution used in the particular analysis (Swofford et al. 1996). The general time reversible model is the most general stochastic model of nucleotide substitution. It models base substitution as a random Markov process in which substitution rates are independent among sites, constant in time, equal in two lineages, and that the ancestral sequence base frequencies represent the equilibrium frequencies (Rodriguez et al. 1990). The GTR model has a maximum of 12 different substitution rates (estimated from the data and using the
aforementioned assumptions in their calculus) as expressed in the above Q matrix (Eq. 7) and at least seven parameters (Rodriguez et al. 1990). Because of its greater complexity, nearly all models (including JC, K2P, K3ST, L, TK, GIN, and TN) can be considered a special case of the GTR model when it is restricted accordingly (Rodriguez et al. 1990). For example, the Jukes–Cantor (often abbreviated JC69) model is the simplest model and assumes that all base substitutions are equally likely (i.e., all rate parameters are equal) and that the base frequency parameters are equal \( f_A = f_C = f_G = f_T \) in the above Q matrix). The K2P model has two rate parameters since it considers differences in rates between transition and transversion type substitutions (Rodriguez et al. 1990). The K3ST model considers three substitution rates, one for transitions and two for each of two types of transversions.

The mathematical procedures of likelihood have several dependencies that are not met in the calculus of maximum likelihood methods. The summation of the probabilities in Eq. 5 does conform to the disjunction criterion of the calculus (Siddall and Kluge 1997). For probabilities to be multiplicative, the change probabilities must be independent. The base compositional frequency parameters in the Q matrix (Eq. 7) are derived from the terminal taxon base sequences over all characters in the analysis (Siddall and Kluge 1997). Rate parameters (relative rate and mean rate) are calculated using the Q matrix (Eq. 6) and the assumption that base frequencies remain constant over evolutionary time (Rodriguez et al. 1990). All sites use the Q matrix to calculate the \( P_{ij} \) values and therefore the probability of any character is dependent on all other characters through the frequency parameters in Q. Characters and their associated probabilities are not independent quantities but are assumed to be in the calculus of the method (Felsenstein 1973, 1981b; Rodriguez et al. 1990; Swofford et al. 1996). The nonindependence of site change probabilities may be one factor responsible for the fact that the total likelihood of the universe of possible trees does not sum to unity (Felsenstein 1981b). The true probabilities for character changes should be calculated on an individual basis because they are connected with unique and historically contingent events (see below), as correctly pointed out by Farris (1973). But this is clearly impossible, as it not only requires knowledge of the true history before undertaking an analysis, it also requires an objective and consistent way of determining the probability of a novel, context-specific evolutionary event (see below, Farris 1973). It would also be computationally impossible (Felsenstein 1973, 1981b; Siddall and Kluge 1997). As currently and commonly employed in phylogenetic maximum likelihood methods, frequency probability theory is technically violated (Yang 1996; Siddall and Kluge 1997).
5.5.4 Choosing a model: more ontological parsimony

The choice of an appropriate model is a critical aspect of a phylogenetic-likelihood analysis. Posada and Crandall (1998) argued that the use of their ModelTest program makes selection of the model objective. There are many models of molecular evolution, and the determination of which to use can significantly influence the results of an analysis. Models range in complexity from the relatively simple Jukes–Cantor model through the most complex GTR model. Currently there are at least 16 models that are commonly used in molecular systematics, most of which are simply special cases of the GTR model (Rodriguez et al. 1990). Each of the 16 basic models is varied with $G$ (gamma distribution), $I$ (proportion of invariable sites), and both ($G+I$) for a total of 56 different models (Posada and Crandall 1998). ModelTest ranks them in terms of their relative complexity (i.e., more complex = more parameters). The overall likelihood score of a tree increases with increasing complexity of the model, but the accuracy of the model decreases due to the increased number of estimated parameters (Huelsenbeck and Rannala 1997a). The program conducts pairwise comparison of the maximum likelihood trees generated under each model using hierarchical-likelihood ratio tests (Huelsenbeck and Crandall 1997; Huelsenbeck and Rannala 1997a; Posada and Crandall 1998; Johnson and Omland 2004). When no statistically significant difference between two trees is found, the simplest model of these is selected. Model selection based on the relative likelihood values is an ontological appeal to the principle of parsimony, because choosing the least complex explanation of the data rules out the possibility that evolution proceeded in a more complex manner (Huelsenbeck and Rannala 1997a).

5.5.5 Criticisms of the models

Many criticisms of maximum likelihood methods are directed at this a priori dependence on a model. Evolutionary realism of the models employed in likelihood analyses is often compromised by approximations that are designed to improve the computational efficiency of the algorithms. For example, Lockhart et al. (1994) suggested that a modified GTR model, in which time-reversibility is relaxed, across site rate variation is considered, and the nucleotide compositional frequencies are flexible, allows more evolutionary “freedom” than any other model, and best considers the historical ambiguity and evolutionary contingency of the evolutionary process. They suggested that this complex, parameter rich, and computationally intensive model should be logically preferred over all other
models, if inferring phylogeny using the most realistic conception of evolution (i.e., evolution is complex) is the goal of the analysis. The problem is that relaxing the time-reversibility assumption introduces the need for rooted trees and is accompanied by additional computational problems (Swofford et al. 1996). Relaxing the assumption that rates are equal across all sites can be accomplished by adding another relative rate parameter to the matrix, which commonly involves modeling rate heterogeneity using the Gamma distribution (Swofford et al. 1996). If this distribution is modeled as continuous (as it should be), it again becomes computationally laborious, and a discrete distribution typically serves as a computationally more efficient approximation (Swofford et al. 1996).

The likelihood method also requires that numerous parameters be approximated using the data, and relies heavily on the frequency parameters that are taken directly from the observed sequences (Swofford et al. 1996). In this sense, likelihood methods require that the processes that maintain systems today were persistent throughout the entire evolutionary history of the clade being investigated (Brooks and McLennan 2002). Siddall and Kluge (1997) and Lockhart et al. (1994) provide an empirical example where the nucleotide frequencies are very different across the terminal taxa, proving that the assumption of equilibrium base frequencies is not at all tenable, and that the assumption of such can affect likelihood phylogenies. When the model is insufficient or inappropriate, appeals to statistical consistency are rendered moot (Siddall and Kluge 1997).

5.5.6 Criticisms of the method

Phylogenetic applications of likelihood rely on two fundamental assumptions: that evolution is independent in different lineages as well as independent in different sites for a given tree, which are essential for the probability calculations on which the method is based (Felsenstein 1981b, 2004; Rodriguez et al. 1990; Swofford et al. 1996). Both assumptions are methodologically problematic because they are unrealistic and/or violated in the calculus (Siddall and Kluge 1997; Huelsenbeck and Nielsen 1999), but likelihoodists appeal to simulations to argue that the method is generally robust to violations of these assumptions (Yang 1994; Swofford et al. 1996). It is also assumed that the same stochastic process of substitution applies in all lineages (Felsenstein 1981b).

and Kluge 1997; Kluge 2001; Goloboff 2003) cite operational and philosophical problems of likelihood methods and discourage its use in phylogenetic inference.

Likelihood methods rely on a specified model of sequence evolution to infer phylogenetic relationships. This is an inductive approach as the assumptions of the model are clearly deterministic to the result of the analysis. In phylogenetic-likelihood analyses, like all inductive approaches in science, all interpretations of the results come with the caveat “if the model is true, then . . . .” Because likelihood is inductive estimation of phylogeny, particular caution must be taken in interpreting the results and to avoid circularity. We may know which of the models best fits the data according to ModelTest, but how can the validity of the model itself be independently tested? Testing of the validity of models, although it has been recognized as important (Goldman 1990), is rarely done in practice (Siddall and Kluge 1997). In a hypothetico-deductive framework, the assumptions of the method are background and not deterministic to the result. Only the observable data is considered, maximizing the explanatory power of the hypothesis and minimizing ad hoc hypotheses (i.e., hypotheses that confide in “nonobservables,” such as long branches in a likelihood framework). It has been argued that many of the simple assumptions of the evolutionary models (i.e., the frequency of transitions versus transversions) constitute grounded knowledge about the process of molecular evolution and therefore is an acceptable background assumption. However, the maximum likelihood approach suggests that this is and has always been the case throughout all situations in the evolution of a group, which is a difficult assertion with respect to the historically contingent nature of the evolutionary process (Siddall and Kluge 1997).

Likelihood methods are based on frequency probability theory. Frequency probability is concerned with prediction of future events (Fisher 1922). The aim of phylogenetic systematics is to discover the unique evolutionary history of a group of organisms, or to elucidate its past (Kluge 1997). A species must be considered a historical entity (Kluge 1990), evolutionary transformations are unique and spatiotemporally restricted historical events (Siddall and Kluge 1997). Frequency-probability based methods of phylogenetic inference, such as maximum likelihood, apply frequency probability to a historical singularity, which is outside of the realm of future-predictive probability theory (Siddall and Kluge 1997). As noted above, likelihood methods assign all trees a nonzero probability, but in reality one tree has a probability of 1.0, and others have a probability of zero. One must be cognizant that maximum likelihood inference of phylogenies is philosophically unsound because it employs frequency probability theory to estimate a nonprobabilistic phenomenon.

In spite of these numerous criticisms, likelihood approaches have become increasingly popular, particularly with molecular phylogeneticists. Recently, other
methods incorporating likelihood logic have become popular in systematics, the most popular of which is Bayesian analysis (Huelsenbeck et al. 2002).

**Bayesian likelihood** Bayesian methods calculate the posterior probabilities of phylogenetic hypotheses (trees) using a version of Bayes’ theorem in which the likelihood of the tree and the prior probability of the tree are considered (Huelsenbeck et al. 2002). Huelsenbeck et al. (2001, 2002) provide excellent recent review of the history and mechanics of Bayesian inference methods in phylogeny.

Reverend Thomas Bayes, living in the early half of the eighteenth century, was an English mathematician who was interested in the concept of using *a priori* knowledge to predict future events. His paper, “An Essay Towards Solving a Problem in the Doctrine of Chances,” published 2 years after Bayes’ death in 1761, introduced what would become known as Bayes’ theorem (Eq. 10; Barnard and Bayes 1958).

\[
P(H|D) = \frac{P(D|H) \times P(H)}{P(D)}
\]

The posterior probability, \([P(H|D)]\), is the probability of the hypothesis given the observations, or data (D). Note that this is different from likelihood, which is the probability of the data given the hypothesis. However, the likelihood, \(P(D|H)\), is a parameter in the calculation of the posterior probability. \(P(H)\) is the prior probability of the hypothesis before the observation, data, or analysis, and reflects the original beliefs regarding the problem. The probability of the hypothesis is updated to take into account the observations, and Bayes’ theorem describes the relationship between the prior and posterior probabilities. It was not until the latter half of the twentieth century that Bayes’ ideas would be applied to the inference of phylogenies. Felsenstein (1968) briefly discussed Bayesian ideas as they could apply to phylogeny reconstruction in his Ph.D. thesis, but the statistical and computational framework with which to derive reliable approximations of posterior probabilities was not available at the time (Huelsenbeck et al. 2002).

Three independent groups introduced Bayesian methods similar to those currently in use in 1996 (Li 1996; Mau 1996; Rannala and Yang 1996). Bayesian methods to estimate ancestral character states have been developed (Pagel et al. 2004; Ronquist, 2004).

Huelsenbeck et al. (2001, 2002) provide overviews of the Bayesian methodology. Bayesian phylogenetic inference evaluates phylogenetic hypotheses with the posterior probabilities of trees. The posterior probability of each tree is calculated using the following Bayes-based equation (Eq. 11), where the tree topology (including branch lengths) is the hypothesis, and the data is typically molecular sequences of the terminal taxa in the analysis.
The likelihood parameter, $P(\text{Data}|\text{Tree})$, is calculated using the same general methodology and same models of molecular evolution described above for the maximum likelihood approach. However, one major difference between Bayesian and maximum likelihood methods is that Bayesian likelihood calculation not only involves summation over all possible combinations of model parameters and branch lengths but also includes a prior probability density distribution of these latter variables (Huelsenbeck et al. 2002). The prior probability of the tree, $P(\text{Tree})$, is usually considered to be equal for all trees a priori (Huelsenbeck et al. 2001). The use of equal priors implies that no particular topology is preferred over any other a priori and eliminates the sometimes difficult task of calculation of complex priors when hypotheses vary with respect to their preconceived probabilities. However, the prior for any given tree or set of trees can be set to reflect researcher experience, the results of previous analyses, or taxonomy (Huelsenbeck et al. 2002). The denominator, simplified here as $P(\text{Data})$, is a normalizing factor that involves summation over all trees (Huelsenbeck et al. 2002). The posterior probability, $P(\text{Tree}|\text{Data})$, can be viewed simply as the probability that the tree is “correct,” given the data, the priors, and that the model of character change used in the likelihood calculation is correct (Huelsenbeck et al. 2002). There are several ways to present the results of a Bayesian analysis. The tree with the maximum posterior probability can be selected as the preferred phylogenetic hypothesis, this is also known as the MAP, maximum a posteriori, estimation of phylogeny (Huelsenbeck et al. 2002). Another method is to construct a 95% credibility consensus tree by starting with the MAP and consecutively adding the next most probable trees until the probabilities total 0.95 (Huelsenbeck et al. 2001, 2002). The method preferred by Huelsenbeck et al. (2002) is to present a summary of the results on the MAP or another consensus tree, as is typically done with bootstrap.

5.5.7 Posterior probability estimation using Markov chain Monte Carlo

Calculation of the posterior probability of a tree is computationally expensive because it involves summation over all possible trees, and for each tree requires integration over all possible permutations of branch lengths and substitution-model parameters (Huelsenbeck et al. 2001, 2002). This is not possible in most practical applications due to computational and time constraints, and requires
that posterior probabilities be approximated (Huelsenbeck et al. 2002). Markov chain Monte Carlo (MCMC) methods are used to approximate the posterior probabilities of trees, and allow contemporary Bayesian methods to be computationally feasible (Tierney 1994; Huelsenbeck et al. 2001, 2002). The MCMC method is used to sample the posterior probability distribution of trees. The application of the MCMC to phylogeny inference is discussed in detail by Mau and Newton (1997), Yang and Rannala (1997), Mau et al. (1999), Larget and Simon (1999), Newton et al. (1999) and summarized in Huelsenbeck et al. (2001, 2002) and Pagel et al. (2004). The general process MCMC is used to approximate the posterior probability density is as follows. First, a random tree is selected. Second, another tree is proposed by changing one variable of the original tree (e.g., topology, branch length, model parameters, etc.), and the two trees are compared using the Metropolis–Hastings algorithm (Metropolis et al. 1953; Hastings 1970; Green 1995; Huelsenbeck et al. 2002). If the tree represents an improvement, it is accepted, or sampled. If not, the tree is either accepted or rejected proportional to the likelihood ratio between it and the previous tree (Pagel et al. 2004). The chain stabilizes after a sufficient period of run time (called the “burn-in”). Once stable the chain randomly walks through the universe of trees, sampling each tree in proportion to its frequency in the actual posterior density (Pagel et al. 2004). The longer the chain is run, the greater precision with which the actual posterior distribution of trees is approximated (Pagel et al. 2004). Metropolis-coupled MCMC uses multiple, simultaneous Markov chains, improves mixing and convergence, and allows exceedingly large data sets that are beyond the scope of conventional single-chain MCMC Bayesian methods to be analyzed (Geyer 1991; Huelsenbeck et al. 2001, 2002).

5.5.8 Advantages of Bayesian likelihood

A major advantage of the Bayesian method is the ease with which posterior probabilities can be interpreted (Huelsenbeck et al. 2002). Under the assumption that the evolutionary model is true and that the MCMC has accurately sampled the posterior probability distribution, the posterior probability value represents the probability that the tree is correct given the data and the priors. Similarly, the proportion of trees in the MCMC sample in which a monophyletic group appears represents the probability that the clade is “true,” given the caveats of priors, model, and data.

As in maximum likelihood analyses, the result of the Bayesian analysis is dependent on the model of sequence evolution being “correct.” Bayesian approaches to phylogeny require a likelihood value of a given tree topology for
their calculation of the posterior probability of that evolutionary scenario. The likelihood parameter in the Bayesian method uses the same models and their associated assumptions as the maximum likelihood methods described above, and the caveats inherent in maximum likelihood phylogeny estimation with respect to evolutionary models also apply to Bayesian analysis (see above discussion of likelihood criticisms).

Computational and time constraints require that the posterior probability distribution be approximated using MCMC techniques (Huelsenbeck et al. 2001, 2002). Chains may fail to provide an accurate estimate of posterior probability distributions if they are not allowed to run long enough, or if mixing is a problem due to widely separated peaks in the distribution. It is difficult to know when a chain has run long enough to provide an acceptable estimate of posterior probabilities. The longer the chain is run, the more precise the estimate of posterior probability distribution. Huelsenbeck et al. (2002) propose three recommendations to ensure that the posterior probability is sampled reliably: (1) run several long chains, and check for consistency in results; (2) run multiple chains, each starting from a random tree and check for consistency; and (3) monitor the model parameters for convergence. The Metropolis-coupling technique promotes good mixing and increases the speed of convergence (Huelsenbeck et al. 2001, 2002).

Some view it as an advantage that Bayesian analysis requires the incorporation of previous knowledge or beliefs in terms of prior probabilities. The mechanics of formulating priors can be difficult if one chooses to base these off the results of previous analyses or taxonomy ("complex priors," Huelsenbeck et al. 2002). Making the prior probabilities of each tree equal eliminates the use of complex priors, as well as any a priori assumptions that any hypothesis is more probable than any other in light of prior beliefs, clearly this approach is not in the true Bayesian spirit.

### 5.5.9 Criticisms of Bayesian likelihood

Bayesian approaches to phylogeny require a likelihood value of a given tree topology (i.e., phylogenetic hypothesis) for their calculation of the posterior probability of that evolutionary scenario. The likelihood used in the Bayesian method requires the same models and their associated assumptions as the maximum likelihood methods described above, and thus all of the cautions inherent in maximum likelihood phylogeny estimation also apply to Bayesian analysis (see above discussion of likelihood criticisms). Analogous to likelihood, the posterior probability of a tree involves summation over all possible trees,
including all their possible permutations in terms of branch lengths and substitution-model parameters (Huelsenbeck et al. 2002). This is impossible to perform in most practical applications due to computational and time constraints, and requires that posterior probabilities themselves must by necessity be approximated. Additionally, Bayesian methods require further assumptions about the prior probabilities associated with each tree. Making the prior probabilities of each tree equal minimizes any a priori assumptions that any topology is more probable than any other.

Harper (1979) had considerable foresight in devising a Bayesian framework aimed toward constructing and testing phylogenetic hypotheses, although this method was largely conceptual and significantly differs from the current practice of Bayesian inference in phylogeny. Likewise, Brooks et al. (1986) proposed the D measure, based on the statistical entropy calculations in information theory. Tribus and McIrvine (1971) suggested that Van der Waals proposed the first link of Bayesian reasoning to statistical concepts of entropy in 1911, when he suggested that the highest entropy state for a system was its a priori most probable state. Lewis (1930) subsequently suggested that increases in entropy were associated with losses of information, and Shannon (1948) used the statistical formulation of entropy as a synonym for expected uncertainty as a foundation of information theory. Kullbach (1951) reinforced the link between information theory and Bayesian reasoning by using the term surprisal (first introduced by R. Levine) as an indicator of departure from the most probable/most expected state. Brillouin (1951, 1953, 1962) showed that there was consistency between Shannon’s use of entropy in information theory and the use of entropy in statistical mechanics and probability theory. Jaynes (1957a, b) derived the formal relationship underlying this consistency and proposed the first entropy maximization principle, in which the maximum entropy state of a system could be formally construed as the most probable state. Parenthetically, and with respect to our discussion of maximum likelihood analyses above, Jaynes’s use of the maximum entropy principle provided a rationale for choosing the most complex, rather than simplest, model for explaining a complex system. He reasoned that adopting the most complex model among all those that explained a system completely would expose our ignorance of possibilities while adopting the simplest would give us a false sense of security, leading us to think we had more complete knowledge than we had.

Gatlin (1975) added to this conceptual framework by discussing two forms of redundancy in the context of biological (specifically DNA sequence) evolution. R-redundancy results from the repeated occurrence of the same symbol in order to get a message across. This is one way to ensure proper communication of a message, but since each symbol must be repeated, R-redundancy is also associated
with reduced message variety. D-redundancy, or Shannon redundancy, results when a single symbol appearing once always subsequently stands for the same thing. D-redundancy is associated with increased message variety, since no symbol need be repeated and thus a larger number of possible messages could be transmitted using the same number of symbols than for situations in which some symbols were repeated. This state may also be associated with reduced message fidelity, however, since missing the symbol initially results in a loss of information subsequently, without hope of a recurrence of the symbol. Gatlin associated D-redundancy with optimal coding in communication systems. Finally, R-redundancy is associated with low information density per symbol (each symbol represents only itself) and D-redundancy with high information density per symbol (each symbol represents many observations).

Brooks (1981) first showed that phylogenetic systematics operationally produced the lowest possible informational entropy configuration for a set of observations over a given set of taxa. This corresponds to the state of greatest difference between $H_{\text{max}}$ and $H_{\text{obs}}$, or the configuration closest to $H_{\text{min}}$ possible given the data. Brooks et al. (1986) later proposed an informal link between this and Gatlin’s D-redundancy, proposing the so-called D-measure for choosing optimal phylogenetic trees on the basis of maximum information density.

Neither Brooks (1981) nor Brooks et al. (1986) related these discussions explicitly to Bayesian reasoning, but there is a clear connection. Following Jaynes (1957a, b), Bayesian approaches in information theory are thus those for which the a priori subjective hypothesis is determined by the entropy maximum principle—the a priori most probable result is the $H_{\text{max}}$, in direct analogy is with the maximum entropy state being the most probable for a closed system. This analogy works in a Bayesian framework if we stipulate that the set of observations we are using in any analysis is a closed subset of all possibilities, i.e., we stipulate that our estimate of $H_{\text{max}}$ is based on a subjective subsample of an imperfectly known universe of characters, and we will not introduce additional observations during the testing procedure.

The entropy maximum is not only analogous to the a priori expected most probable state, it is also the state of lowest information density of the observations, hence least informative, hence least surprising (in a Bayesian sense). For any set of observations (subjective in the sense that they are a subjectively selected subset of all observations, drawn from a universe for which we do not have any sense of the actual size or distribution of variables—even if the observations are obtained objectively), we can objectively compute the most probable state ($H_{\text{max}}$). We can also objectively compute the least probable state ($H_{\text{min}}$), which is the state of greatest information density for the observations, and thus the state of greatest surprise.

198
The most powerful analysis of such data is one that seeks to find the most improbable/highest information density configuration permitted by all the data at hand. For phylogenetic analysis, $H_{\text{max}}$ and $H_{\text{min}}$ can be calculated from the basic data matrix (hence $H_{\text{max}}$ is \textit{a priori}), whereas $H_{\text{obs}}$ is calculated over a set of trees (hence, it is \textit{a posteriori}). The preferred result is the one in which $H_{\text{obs}}$ approaches $H_{\text{min}}$ as closely as possible.

Applying the D measure leads to a number of conclusions for phylogenetics analysis (Brooks et al. 1986): (1) information density is proportional to evolutionary conservatism; (2) dichotomous solutions are preferred over polytomies, as each instance of conservative evolution increases information density; (3) branching topology is irrelevant, there is no \textit{a priori} difference between symmetrical and asymmetrical tree structure in terms of information density, since it is the information that produces the tree, not the reverse; (4) for any data set, the most information dense set of relationships of all taxa over all characters allowed by the data is the shortest tree; and (5) when there are multiple most parsimonious trees, ACCTRAN provides a more information dense summary of the data than DELTRAN.

This version of Bayesian thought applied to phylogenetics, therefore, devolves to straightforward support for Hennigian methods. Missing from this formalism are statistical significance tests. There need to be two of them: first, is the result significantly different from the \textit{a priori} expectation ($H_{\text{max}}$); and second, are less information-dense alternatives (e.g., other equally parsimonious trees or less than most parsimonious trees) for the same set of data significantly different from each other?

### 5.6 How do you decide what method(s) to use?

We have discussed a variety of objective methods for pursuing quantitative phylogenetic analysis. We believe, however, that there are no objective means by which one can choose among these methods. Consequently, it is no surprise that some of the most contentious interactions among phylogeneticists concern the very subjective issue of which methods are “best” or “proper” or “correct.” It is common for groups of contending scientists, faced with such a situation, to resort to philosophical arguments in an attempt to claim priority for one viewpoint over another on the basis of some set of first principles. This has certainly been the case with phylogenetics.

#### 5.6.1 Popper

The first salvo fired in this conflict was by Wiley (1975), who, defending phylogenetic systematics against claims that it was not falsifiable, proposed that
phylogenetic hypotheses of homology could be seen as an exercise in hypothetico-deductive reasoning

> Once a hypothesis of homology is formulated from the world of experience it is tested in two phases: by its own set of potential falsifiers and by a set of potential falsifiers of the phylogenetic hypothesis to which it belongs as a proper subset (i.e., it is tested by other hypotheses of synapomorphy through the testing of the phylogenetic hypotheses which they corroborate). Both phases of testing must be done under the rules of parsimony, not because nature is parsimonious, but because only parsimonious hypotheses can be defended by the investigator without resorting to authoritarianism or apriorism. Wiley (1975) p 236

Hypotheses of homology, together with their connected hypothesis of phylogenetic relationships, can be tested by other independently proposed homologies, which then represent the so-called potential falsifying hypotheses (Popper 1968 p 87). Wiley emphasized that such a process is not circular, but represents a case of “reciprocal illumination,” something Hennig (1966) also claimed. Wiley noted that the preferred phylogenetic hypothesis is the one that has been refuted the least number of times. That Hennigian phylogenetics was justified by the hypothetico-deductive approach of Popper quickly gained support (e.g., especially Gaffney 1979) and still has strong adherents (Kluge 2003) who consider Hennigian phylogenetics to be strongly deductive in nature.

Recently de Queiroz and Poe (2001, see also Faith and Trueman 2001) attempted to link Popperian thought with likelihood approaches, suggesting that likelihood is the basis for Popper’s degree of corroboration. However, for Popper, corroboration was embedded in a falsificationist context, whereas these authors sought to decouple Popper’s ideas about corroboration from those about falsificationism. In this context their degree of corroboration is identical with Popper’s formalization of degree of confirmation (Popper 1997 p 222). This seems to get us nowhere, since it leads back to the position that if a model is accepted as true, or highly typical, its use is justified. But, no objective means is provided for verifying or falsifying the validity of the model beyond the arguments about statistical consistency whose shortcomings we discuss next. Regardless of semantic arguments about corroboration and confirmation, and possibly a high degree of revisionist interpretation of Popper’s views on the relationship between corroboration and falsification, these arguments do not counter the basic observation that maximum likelihood methods are more inductive than deductive in nature. And, if the difference between what we have characterized as the epistemological and the ontological parsimony approaches is the difference between a preference for deduction and a preference for induction, the history of science tells us that there is no objective means for choosing between them.
However popular it has been among some systematists, this battle of philosophical perspectives has been subject to extensive criticism by philosophers, best summed up by Sober (1988), who identified phylogenetic analysis as abductive, that is, neither exactly deductive nor exactly inductive. This is explained by the fact that the phylogenetic inference is retrodictive analysis of historically unique events. Among other things, this means that inference from effects to cause(s) is ampliative. As systematists, we can only observe the effects under the causal theory of descent with modification (i.e., observable synapomorphies), but possible causes for conflicting data are also reversals and parallelisms. Thus, multiple conclusions about the cause(s) are possible in phylogenetic inference. By contrast, true deduction is nonampliative, enabling inferences from cause to effect(s), with singular conclusions for any given analysis.

### 5.6.2 Statistical consistency

A method is said to be statistically consistent if it converges on the true tree as progressively more character data is added to the analysis. One reason likelihood has gained popularity in the last two decades is that it has been suggested that other methods of phylogenetic inference, namely Hennigian parsimony, are statistically inconsistent under certain, largely hypothetical models of evolution (Felsenstein 1978; Penny et al. 1992). The region of statistical inconsistency has been referred to as the “Felsenstein Zone,” and it is the result of a process termed “long-branch attraction.” The long-branch attraction problem occurs when convergent homoplastic changes are more frequent than nonreversed changes in an informative part of the tree (Felsenstein 1978). This confounds Hennigian phylogenetic systematics because, under the Auxiliary Principle, the convergent homoplasies will tend to be considered as homologies and thus the taxa with their convergent “long-branches” will be grouped together (Hennig 1966; Felsenstein 1978). In simplest terms, when the data are lying about the relationships of the taxa, phylogenetic systematics (i.e., Hennig 1966) may fail to discover the true relationships. How often this occurs in nature is unknown, but Huelsenbeck (1997) has cited one case involving insects as exemplifying the long-branch attraction problem in a real data set (but see Siddall and Kluge 1997 pp 319–320). The concern that “noise,” or random data, misdirects phylogenetic systematics is also overblown (Wenzel and Siddall 1999).

Maximum likelihood has been reported to exhibit the favorable property of statistical consistency in the face of these situations (Felsenstein 1978; Penny et al. 1992; Yang 1994). It is true that in statistics the maximum likelihood estimate of a parameter is consistent (Fisher 1922; Edwards 1972). Simulation experiments
have shown this to be true in the phylogenetic context (Yang 1996), but only when the same random model used to generate the data is used and/or only when a certain correction factor is implemented (Steel et al. 1993; Siddall and Kluge 1997; Steel and Penny 2000; Goloboff 2003). It is an important caveat that maximum likelihood methods are only consistent (i.e., converge on the “true tree”) under a certain set of circumstances which typically requires that the “correct” model is used, but that the correct model and the true tree are both unknowable for real systems.

Farris (1973) suggested a protocol by which parsimony methods could be interpreted as derivatives of statistical estimation methods. This probabilistic view of parsimony was critiqued by Felsenstein (1973, 1978, 1981a, b, 1983), who focused on the statistical deficits of parsimony when viewed as a likelihood method. In general, parsimony and likelihood approaches produce the same results under the assumption of particular parameters for parsimony, i.e., low rates of evolutionary changes or equal rates of evolution among the observed lineages, or low rates of homoplasy (Felsenstein 1983). It has also been demonstrated that parsimony-based methods can be consistent (Steel et al. 1993; Siddall and Kluge 1997; Steel and Penny 2000, with a correction factor). Siddall and Kluge (1997) and Steel and Penny (2000) correctly point out that all methods are potentially consistent or inconsistent (Steel et al. 1993). Statistical consistency is not a property of a method, but the property of a specific data set, the model, and specific situations.

Likelihood methods generally require that the processes maintaining current systems were always present and consistent in the past, and this is likely not the case. Models range from relatively simple to complex, but all make approximations for computational efficiency that impair evolutionary realism. When the model is insufficient or inappropriate, as is common, arguments of statistical consistency are rendered moot. As noted earlier, frequency probability theory is violated in the calculus of current maximum likelihood methods (due to violation of independence requirements). Maximum likelihood uses a method intended to predict the future out of a range of simultaneously possible outcomes to infer a nonprobabilistic historical singularity, the evolutionary relationship of organisms.

It appears that neither epistemological nor ontological parsimony methods for inferring phylogenies can be justified, or given precedence over the other, by any part of Popper’s philosophy. Nor can either approach be given priority by appeals to statistical consistency. And, finally, each approach can be given a Bayesian interpretation. Is there an objective way to choose between, or to reconcile these subjectively divergent approaches?

An appeal to collegial pluralism (Faith and Trueman 2001) seems like a good idea at first glance. It is becoming a common practice for an author to present
maximum parsimony, maximum likelihood, and Bayesian analyses of the same data, then either arbitrarily to express a preference for one of them, or to present a consensus tree of the outcomes of each analysis, and using that as “the phylogeny.” We do not believe this is a useful approach. In the first case, the arbitrarily chosen result inevitably is the one that best supports the evolutionary scenario advocated by the author, which actually weakens the author’s case that the result emerged uniquely from the data. In the second case, a consensus tree effectively hides precisely the parts of analyses that are in need of additional scrutiny, giving author and audience a false sense of security about the results.

We believe that individual data analyses without reference an explicit evolutionary model or hypothesis (i.e., epistemological parsimony) are not explanations. They are descriptions, admittedly highly sophisticated descriptions, but just that. Fitting data to a model provides explanations, but does not give any means of testing the veracity of the model or its assumptions. Independent description and assessment relative to explanatory models both appear to be necessary but not sufficient for robust explanations. Or,

- If models do not agree with the empirical data, chances are the models, not the data, should be reevaluated. This is not an antimodel stance. A mutually reinforcing and mutually modifying dialogue between models and empirical discovery enhances progress. Brooks and McLennan (2002)

Kluge (1989, 1991, 1997, 1998a, b, 1999) has argued persuasively that historical sciences progress through cycles of discovery and evaluation, both of which are necessary but neither of which is sufficient for complete understanding, and both of which require objective methods of study. We believe that Hennigian (epistemological parsimony) analysis is the best discovery method we have in phylogenetics. This is because its results are dependent on a minimum of a priori assumptions and thus the range of potential discoveries indicated by the data is greater than for any ontological parsimony approach. At the same time, we believe that this feature of Hennigian phylogenetics renders it relatively weak as an instrument of evaluation.

It appears to us that the various maximum likelihood and Bayesian likelihood approaches are admirably suited as evaluation methods. We would like to see epistemological and ontological parsimony methods used together in a form of reciprocal illumination, not in the narrow sense of deriving a tree from multiple characters, but in a broader sense of cycles of discovery and evaluation. How would this work?

To begin with, suppose a Hennigian analysis, a maximum likelihood analysis, and a Bayesian analysis produce the same result? We should all celebrate because we would have a relatively independent discovery (the Hennigian
tree) supporting an evolutionary model (the likelihood tree). In this case, no one should have any concerns using the likelihood model to infer divergence rates on the Hennigian tree. Now, what does it mean if these different analyses do not produce the same result? The findings by Rokas et al. (2003) suggest that all such situations are an indication that not enough data have been used. Their total-genome (107 gene sequences) analysis of a clade of 7 yeast species showed that a minimum of 20 genes (i.e., roughly 20% of the genic characters possible) was required to ensure that all methods produced the same phylogenetic tree. Different methods gave different results when not enough characters were used to compensate for ambiguities of various kinds in the data, which are handled in different ways by the different methods discussed in this chapter. These results were anticipated experimentally by Hillis et al. (1992, 1993; Huelsenbeck and Hillis 1993), who produced a phylogeny for bacteriophages maintained in the laboratory. They discovered that most model-based approaches and Hennigian phylogenetics converged on the same, and true (since it was known) phylogeny as more and more traits were sampled. These results would seem to suggest that the primary response to any situation in which the different approaches to phylogenetics produce different answers should be

What do we do while we are waiting for enough data to give the same answer with all methods? Hillis et al. (1992, 1993; Huelsenbeck and Hillis 1993) showed that when a limited amount of data are available, some models generate the correct phylogeny better than Hennigian approaches. Although this finding has been interpreted by some as an indication that model-based methods are inherently superior to Hennigian methods, Hillis et al. (1994) pointed out a significant trade-off. Model-based approaches provide a distinct answer based on little data, but the confidence you have in that answer is proportional to your belief that the model used accurately reflects the evolutionary process over extended periods of time for the clade you are analyzing.

The issue becomes–how do we know the model typically gives the truth? Hillis et al. (1992) took a critical first step by generating an experimental phylogeny. The next step is to ask how typical of evolution is that phylogeny? Remember that the phylogeny (1) involved bacteriophages and (2) was generated in the laboratory according to rules invoked by the researchers (reminiscent of the Caminalcules to develop one of the first epistemological parsimony algorithms). Some have suggested that prokaryote evolution has produced not a phylogenetic tree but a highly reticulated network (Doolittle 2000), in which case the experimental phylogeny produced by Hillis et al. (1992) is not typical of evolutionary
history for their model organisms. Nonetheless, their results may still be typical of phylogenesis for eukaryotes.

More important is the question, how large a role has the historical contingency that is such a critical part of Darwinian mechanisms played in phylogenesis? Some have asserted that such contingencies do not affect phylogenetic reconstructions while others have asserted the opposite (see Yang and Bielawski 2000 for a review). Seen in this light, is it possible that the reason Hennigian and model-based approaches converge with increasing data is that the more data we consider, the more historical contingencies will play a role, in which case model-based approaches will progressively choose models whose set of “allowed possibilities” most closely approximates the minimal “a priori restrictions” of Hennigian phylogenetics. For example, Gissi et al. (2000) reported lineage-specific evolutionary rates for different mammalian mtDNA genes, suggesting that recovering the correct phylogeny might require a different mode for each gene, and used their findings to support contentions by other molecular systematists that, given uncertainty about the true phylogeny, we cannot know which model will give the correct phylogeny, and thus we do analyses of as many genes as possible to help determine the appropriate model (Mitchell et al. 2000). For those researchers, the appropriate response to the assertion that “Nature is not as simple as our models . . . . But this should not be taken as a criticism of the use of a model” (Pagel 1992) is, “Yes, it should” (Wenzel and Carpenter 1994).

Once again, we are faced with a conundrum. We suggest that the next step involves a form of reciprocal illumination. That is, use the Hennigian result, rather than Model Test, to determine the best likelihood model (i.e., what likelihood model gives the Hennigian tree). Then use the implied divergence rates from that model to add an explanatory context to the phylogenetic description without fear of introducing an element of circularity (by using the same model to build the tree that you want to test using the tree). When repeated across a variety of clades, this approach might suggest that some models fit the data more often than others, thus shedding light on the general process of evolutionary divergence patterns and rates. Perhaps some models would be suitable so rarely that they could be excluded from consideration of such general processes.

Similarly, one could use the maximum likelihood model “chosen” by the Hennigian analysis to assess the accuracy of the phylogenetic reconstruction, e.g., by linking the inferred divergence times with biogeographic or stratigraphic data. A likelihood framework has been used to incorporate or evaluate the probability of the phylogenetic hypothesis given the stratigraphic (i.e., temporal) distribution of taxa in the fossil record (Huelsenbeck and Rannala 1997b; Wagner 1998). These analyses require additional assumptions about the completeness of the fossil record and the reliability of the stratigraphic correlations. Wagner (1998)
presented an analysis of hyaenids in which the strato-likelihood tree was 10 steps longer than the most parsimonious tree, but it was putatively more consistent with the fossil record of the taxa. If the phylogenetic tree corresponds to a model that is in stark contrast with fossil evidence, its time to get more data and reassess your tree, and also time to dig for more fossils.

5.7 Conclusions: Special concerns for paleoanthropology

This is an exciting time for paleoanthropologists to be involved in evolutionary biology. New discoveries of previously unknown primates and new fossil material of poorly known taxa are constantly changing our perspectives on how our closest relatives evolved and behaved. Phylogenetic systematics is a powerful investigative tool for generating and evaluating new evolutionary hypotheses. Its power lies in its transparency and paucity of assumptions; rather than appealing to the authority of what we “already know,” parsimony analysis generates hypotheses allowing the raw data speak for themselves.

Phylogenetic systematic methodology has become widely accepted among anthropologists and paleoanthropologists in particular; most generally acknowledge its applicability to evolutionary studies of the primates (Groves 1978; Strasser and Delson 1987; Disotell 1996; Begun et al. 1997; Rae 1997; Ross et al. 1998; Harris 2000; Begun 2001; Newman et al. 2004). Many of these studies have revealed aspects of primate relationships that were previously unknown and have pointed to new avenues for research. For example, Begun’s (2001; Begun et al. 1997) analyses of 14 taxa and 240 and 247 characters, respectively, suggests that Eurasian late Miocene hominoids (Dryopithecus and Ouranopithecus) are the sister taxa to the African ape–human clade. We can use this hypothesis to draw inferences about Miocene hominoid biogeography; Begun mapped the areas in which hominoids are found onto the cladogram to demonstrate that the most parsimonious optimization is of a Eurasian origin of the African ape–human clade. Likewise, it is possible to map characters onto the tree to explore how certain characters evolve. It should be clear that to avoid circularity, the tree must be robust enough to maintain its topology without the characters under investigation (Brooks and McLennan 2002).

Phylogenetics is not without detractors in the anthropological community. Some have suggested that complicating factors specific to hominids may result in fallacious results using phylogenetic systematics (Andrews 1992; Lieberman 1999; Collard and Wood 2001; Hawks 2004). In a recently published article, Hawks explored the degree to which cladistic methodology is able to clarify
relationships within hominids. He cited difficulty with character choice, character independence, atomizing continuous traits, and coding polymorphic characters as key causes undermining the reliability of phylogenetic methodology. These factors are not restricted to hominid systematics; they constitute some of the most important and subjective decisions in phylogenetic research. There is no real consensus on how to code morphological characters, or even what constitutes a good character. A character is merely an observed part or attribute of an organism (Colless 1985), assumed to be heritable. The nature of characters is clade-dependent, and the usefulness of any particular character in a phylogenetic analysis will be directly related to whether it is a synapomorphy or not. Of course, we do not know whether a character is synapomorphic until we run the analysis, based on as large a number of characters as possible.

Concerns about character choice are based on the notion that a set of characters that have all evolved in concert, yet in parallel, as a result of convergent selection vectors, could produce a robust Hennigian result that was nevertheless an incorrect depiction of phylogeny. Collard and Wood (2001) suggested that correlated functional convergences in catarrhine face and jaws made phylogenetic analyses using only those characters unreliable. This is a problem for paleoanthropology, in which the majority of fossil remains are exclusively, or nearly so, crania and teeth (Strait et al. 1997). It is true that for any data set in which correlated homoplasies outnumber homologies, Hennigian methods will produce an incorrect result. In the Hennigian system, however, homoplasies are not known a priori, so correlated homoplasies cannot be known a priori. Therefore, we must assume character independence alongside the presumption of homology. This has recently been dubbed Kluge’s Auxiliary Principle (always presume character independence in the absence of evidence to the contrary) (Brooks and McLennan 2002). This principle asserts that the identification of potential cases of correlated homoplasies begins with a phylogenetics analysis, which identifies correlated traits. Once historically correlated traits have been identified, a researcher can ask whether or not they have unduly influenced the results. If reducing the number of phylogenetically correlated traits that come from a single part of the body significantly alters the phylogenetics hypothesis, only then is it reasonable to discuss the possibility of correlated homoplasies affecting our phylogenetics reconstructions. Similar reasoning applies to the coding of continuous (meristic) and polymorphic traits. Both pose theoretical and methodological problems for the interpretation and optimization of characters on the tree. For example, the “polymorphism” setting in PAUP* does not allow hypothetical ancestors to possess the polymorphic condition (Swofford 1998). This is a default to maintain tree length at a minimum. PAUP* treats polymorphic taxa as
heterogeneous, however some programs treat taxa possessing multiple states as missing data (Wiens 1995).

Finally, we must remember that phylogenetic analysis of any kind is merely an analytical tool. If the results of a Hennigian analysis are not what we expected, there is nothing in the methodology that requires that we believe that the results of any given analysis are true. Rather, we are faced with several possibilities: (1) the data are lying to us and no amount of additional data will rectify the problem, (2) the method is flawed, or (3) we do not have enough data. If we opt for the first two possibilities, we must then choose a model that better fits our beliefs, experience, or understanding of the evolutionary process than do the data, then reconcile the data to the model.

If we opt for the third possibility, we need to be exhaustive and explicit in character choice, to include new data and reevaluate our hypotheses frequently, and to use independent data to corroborate or refute those hypotheses. Phylogeneticists must be explicit about the methods they use to generate and evaluate trees, and those evaluating their publications need to be aware and informed of the methods used. A list of character descriptions as well as the data matrix used to generate the tree should be available so that other researchers can evaluate the authors’ character codes. Consistency indices, decay analyses, and consensus trees are important procedures for assessing the robustness of results, and should be published. As well, the techniques employed to generate these results should be clear. Other elements to consider when generating or evaluating phylogenetic hypotheses include: Do independent data (e.g., fossil dates, biogeography, behavior) corroborate or refute the hypothesis? Were all known taxa included? If not, is it because of “poor preservation, or lack of adequate sample size”?

This transparency will facilitate discussion and evaluation of various characters, and allow us to test hypotheses that, for instance, craniodental characters exhibit more correlated homoplasy than postcranial characters (Collard and Wood 2001). It will lead to discussions of functional correlations of characters, and eventual reevaluation of character choice and coding, strengthening the phylogenetic hypotheses we create. While the goal of a phylogenetic analysis is to reconstruct relationships based on shared, derived characters, the really interesting evolutionary enigmas in any clade are the homoplasies. These convergences and parallelisms direct our attention to possible functional or environmental selection responsible for the visible pattern of evolutionary change. Or,

▷ [there are] . . . four guiding principles: (1) phylogenetic trees are necessary but rarely sufficient for explaining evolutionary origins and diversification; (2) we must always be responsible for well-formulated questions; (3) we must always
be responsible for the quality of the data used in any level of our analyses, from generating phylogenetic hypotheses to testing general theories; and (4) everything we learn implies yet more cycles of discovery and evaluation . . . Brooks and McLennan (2002)

Acknowledgments

We thank the editors for inviting us to contribute to this volume. For their participation in a graduate seminar course entitled “Foundations of Phylogenetics,” we thank Jaret Bilewitch, Charmaine Condy, Nikolas Gour, Dominik Halas, Stephanie Hill, Michelle Mattern, Robert Murphy, Richard Winterbottom, David Zamparo, and David Zanatta. DCE, JF, KEF, and LAT thank Robert Reisz and Johannes Müller for thought-provoking discussions. DRB, DCE, and KEF acknowledge funding support from the Natural Sciences and Engineering Research Council (NSERC) of Canada. JF acknowledges support from the Government of Canada Awards.

6 Homology: A Philosophical and Biological Perspective

Olivier Rieppel

Abstract

Current discussions of the concept of homology center on metaphysical and epistemological issues: what are homologs, and how can they be discovered? Homology is the relation of common ancestry shared by homologs. Homologs are the “same” parts of two or more organisms under every variation of form or function that are shared due to inheritance from a common ancestor. Homology is the key to phylogeny reconstruction, because the hierarchy of homologs/homologies is isomorphic with the phylogenetic hierarchy of taxa. Consequently, the discussion of homologs as evolving entities shares many parallels with the discussion of species evolution. Homologs are conceptualized as tokens of natural kinds that engage in causal processes of ontogeny, phylogeny, and physiology. Operational criteria for the discovery of homology are the topological relations (connectivity) shared by homologs. These operational criteria are (at least to some degree) grounded in ontogeny, where developmental modules may share the relation of homology. In that sense, the operational criteria for the discovery of homology are aligned with the structure of the causal processes in which the homologs qua tokens of natural kinds engage. The discussion of concepts of partial homology and the complementarity of static (taxic, hierarchical) versus dynamic (developmental, transformational) approaches to homology reveals empirical as well as a semantic components.

6.1 Introduction

The pretheoretical use of the concept of homology reaches far back into the preevolutionary history of comparative biology (Panchen 1994). Belon (1555) is usually taken as locus classicus for the earliest illustration of the relation of homology (Figure 6.1), although the concept must have been implicit in Aristotle’s recognition of dolphins as mammals (Russell 1982 p 6).
Figure 6.1
In a comparison of the skeleton of man and a bird, Belon (1555) recognized the topological equivalence of constitutive elements (courtesy of the Field Museum Library, Mary W. Runnells Rare Book Room)
For Etienne Geoffroy St. Hilaire, the unity of type was based on the relation of “analogie,” a concept that captured the correspondence of relative topological relations (connectivité) of constituent elements of the organism tied together throughout ontogeny by the blood-vascular system (Rieppel 1988, 2001). Geoffroy’s “analogie” became Richard Owen’s “homology”, meaning “the same organ in different animals under every variety of form and function” (Panchen 1994 p 40; Williams 2004 p 192). Owen contrasted this concept with “analogy,” meaning “a part or organ in one animal which has the same function as another part or organ in a different animal” (Panchen 1994 p 40; Williams 2004 p 192). Panchen (1994 p 44) drew attention to the fact that, as used by Owen, homology and analogy were not necessarily mutually exclusive concepts, so a third term was required to characterize structures analogous between two or more organisms but not homologous. This was Lankester’s (1870) “homoplasy.” In fact, Lankester (1870) restricted the use of the term homology to its pre-evolutionary connotations; he called the evolutionary use of the concept that implies common ancestry “homogeny.”

At the hands of Geoffroy St. Hilaire or Owen, homology was meant to capture structural correspondence, rooted in “laws of structure” as expressed during ontogeny. The relation of homology (and analogy) was reconceptualized (Kitcher 1993 p 32) by Darwin (1859), who found that, on his theory, “unity of type is explained by unity of descent” (Darwin 1859 p 206). The term homology continued to apply to the same constituent parts of organisms that were recognized as homologs by Owen, but the meaning of the term changed to something roughly like “shared similarity due to common ancestry.” The history of the concept of homology has been variously sketched, sometimes in great detail (Panchen 1994; Williams 2004), and needs not to be retraced here. Instead, the focus of this chapter will be on issues that are central to the contemporary discussion of the concept of homology in systematics and developmental biology. How does “similarity” relate to the concept of homology, or, in other words, how can the relation of homology be rendered empirically accessible? Is there such a thing as “partial homology”? What does it mean to say, in Owen’s words, that homologs are “namesakes,” i.e., parts that “merit the same name” (Patterson 1988 p 605); or that “the same names can be given to the homologous bones in widely different animals”; (Darwin 1859 p 434). What does “sameness,” “structural identity” (Wagner 1994), or “historical identity” (Grant and Kluge 2004) mean in reference to homologs, or, in other words, what kind of names refer to homologs? Are homologs particulars (individuals), denoted by proper names, or tokens of natural kinds, denoted by general names?
6.2 Semantics of homology statements

To better understand the semantics of homology statements, it is worthwhile to first introduce some distinctions, derived from Lankester’s (1870) terminology (Table 6.1).

### Table 6.1
A comparison of Lankester’s (1870) and contemporary use of the terms homology and homoplasy. For further discussion see text

Homology assessment has been recognized to be, minimally, a two-step procedure (Jardine 1969; Rieppel 1988, 2004a; dePinna 1991; see Brower and Schawaroch 1996 for a more elaborate account). An initial conjecture of homology, based on some similarity relations that obtain between the organisms under analysis, represents an observational statement. The relation expressed by that statement was called homology by Lankester (1870), which corresponds to the “topographic homology” of Jardine (1969 p 357) or the “primary homology” of dePinna (1991). Statements of primary homology are observational statements that relate to the organisms under analysis (Rieppel 2004a). The putative phylogenetic information content of those observation statements is subsequently tested on the basis of congruence (see further discussion later). If the statements pass the test (if they turn out coherent/congruent), they are called homology statements that correspond to dePinna’s (1991) “secondary homology” (phylogenetic homology sensu Jardine 1969). These statements of (secondary) homology imply “similarity due to common ancestry” and therefore are theoretical statements, i.e., theoretical (meta) statements about the observational (object-) statements (Rieppel 2004a). If coherence/congruence fails to obtain, the observation statements are said to be statements of homoplasy, which imply convergent similarity relations or chance similarity. Parallel evolution is said to result in a similarity relation between related lineages that is not inherited from their common ancestor. Consequently, congruence of observation statements (of primary homology) may theoretically be due to parallel evolution, but given the tools of phylogenetic systematics, there is no way to empirically distinguish (secondary) homology from parallelisms. From these considerations, Farris (1983) drew the agnostic (Sober 1985) conclusion that whereas incongruence undermines, congruence does not necessarily confirm phylogenetic hypotheses.
Observation statements deploy predicates that are meant to apply to the objects observed. For example, a chordate is an animal with a notochord, a “renate” is an animal with kidneys. The sentence “a chordate is an animal with a notochord” is of a subject–predicate structure, symbolized as $Fx$, where $F$ is the predicate “... is an animal with a notochord,” $x$ is the subject that is an animal with a notochord. More generally, “chordates” is the set of all animals that have a notochord, renates is the set of all animals that have kidneys. The fact that homology statements deploy predicates (Mahner and Bunge 1997; Wiesemüller et al. 2003) threatens to create an ontological inconsistency in an evolutionary context that is rooted in what philosophers call the “one-over-many” problem: “the selfsame property [e.g., to have a notochord] can be instantiated by numerically different things [e.g., rabbits and tigers]” (Swoyer 2000 p 2). The extension of a predicate is typically taken to be the set of all things to which the predicate truthfully applies: the extension of the predicate “... with kidneys” is the set of all animals with kidneys. But sets are abstract entities, not historical entities, and the semantic value of a predicate is usually taken to be a universal not a particular (but see Swoyer 2000 for further discussion). Homology statements predicate properties of organisms, and properties, in contrast to particulars (individuals such as objects or bodies) are universals (properties include the attributes or qualities or features or characteristics of things) (Swoyer 2000 p 2). Under the paradigm of nominalism, only particulars can claim existence (i.e., the occupancy of a particular space–time region), universals such as properties cannot. If we think of each term as referring to (denoting, designating) a thing (object, body), then predicates would have to refer to entities, with the consequence that universals, such as “redness” ($x$ is red), or “rabbit-hood” ($x$ is a rabbit) acquire some sort of Platonic existence as abstract entities. To avoid this conclusion, Devitt and Sterelny (1999) proposed to conceptualize predicates not as referring expressions but instead as expressions that apply to particulars (which in turn occupy a particular space–time region). For what would be particulars “when stripped of their clothing of universals” (Devitt and Sterelny 1999 p 278)? The predicate “... is red” can thus apply to this or that or yet another apple, the predicate “... is a tiger” can apply to this or that or yet another individual organism.

If the predicate “... is red” is applied to “this apple” (to which I point), then this apple is said to instantiate the property redness, but redness does not exist as a spatio-temporally restricted entity. In contrast, kidneys exist as spatio-temporally restricted entities: they can be removed or replaced by surgery. So what is the difference between “this apple is red” versus “this creature is an animal with kidneys”? One way to look at the issue (Haack 1998 p 133) is to claim that the predicate “... is red” marks out the set of all red things, and apples are (or can be)
members of that set. Similarly, the predicate “... is an animal with kidneys” marks out the kind of all animals with kidneys, i.e., the renates. The set of red things that includes apples, cars, and billiard balls is unlikely to be tied together by a unifying causal process, but the renates, which (for the sake of the argument) are here equated with vertebrates, are tied together by unifying causal processes, namely those of ontogeny and phylogeny. In other words, redness is not a property that is causally efficacious, the set of red things therefore not a natural kind. In contrast, to have kidneys is a causally relevant property that is shared by all renates, and it is in virtue of engaging in these causal processes that renates form a natural kind, as do vertebrates and also apples—red, green, or yellow—but not red things.

Under such analysis, individual tigers become tokens of a natural kind, namely parts of the sum of all tigers. “Tiger” thus becomes a name associated with a natural kind term, and the extension of that natural kind term (of the predicate “... is a tiger”) is the sum of all tigers, i.e., the natural kind tiger that is marked out by a common evolutionary origin. In other words, the common evolutionary origin is the relevant property that marks out the natural kind tiger. Each individual tiger that shares the same evolutionary origin is therefore a token of its kind. Each individual vertebrate is a token of the natural kind “renate”, or “chordate,” if the relevant property that marks out the natural kind “renate” or “chordate” is commonality of evolutionary origin.

Natural kinds come in hierarchies (Platts 1997): the individual lemon is not only a token of its proper kind but also a token of the natural kind “citrus fruit,” as well as a token of the natural kind “fruit.” The same is true for animals: the individual tiger is a token of tigers, of “mammals,” of “vertebrates.” A lemon can be squeezed, a tiger captured, a kidney removed or replaced. The sum of all kidneys constitutes a natural kind, its tokens are instantiated by all renates. “Notochord” is a natural kind term, the tokens of its kind are instantiated by all chordates. Renates and chordates constitute a natural kind, if they share a common evolutionary origin; particular kidneys and notochords (taken from rabbits or tigers) are tokens of natural kinds that share a common evolutionary origin if kidneys and notochords are homologs of vertebrates. If kidneys and notochords were homoplasies (e.g., homoplastic in rabbits and tigers), they would be tokens of nominal kinds (the corresponding terms nominal kind terms). The key to “natural kindness” is the fact that the tokens of the kind take part in causal processes, that their properties are causally efficacious (Sober 1981; Quine 1994; Shoemaker 2003).

Conceptualization of homology in terms of natural kind term semantics offers a key to why homology statements have to be tied to a conditional phrase (Bock 1974), given the fact that natural kinds, as well as homologies, come in
hierarchies. Let us follow Quine (1964) into a foreign country where people speak a language that I do not understand. In that situation, a native points at a passing rabbit and utters “gavagai.” Seeing what the native points at and hearing her utterance does not tell me whether the native means “rabbit,” “rodent,” “mammal,” or “vertebrate,” etc. In a similar sense, the statement that “bird wings and bat wings are homologous” remains underdetermined. Given that statement only, I cannot decide whether it is right or wrong relative to the background knowledge of the currently accepted theory of vertebrate phylogeny. But if the statement is “bird wings and bat wings are homologous as (qua) tetrapod limbs,” I know that the statement is right; if it is “bird wings and bat wings are homologous as (qua) wings,” I know it is false, given the background knowledge (see the discussion of the “qua‐problem” in Devitt and Sterelny 1999).

Homologs have been claimed to be individuals, or historical individuals, on ontological grounds (Grant and Kluge 2004). The reason is that only particulars, or individuals, can take part in causal processes such as descent with modification. Sets, or classes, cannot. If homology is a property, and properties are universals that mark out sets, or classes, then homologs cannot evolve. On the analysis described previously, causally efficacious properties mark out natural kinds. The common evolutionary origin marks out the natural kind tiger, but it is individual tigers, i.e., the particular tokens of the natural kind that engage in causal processes such as descent with modification. If homologous, the sum of kidneys constitutes a natural kind, but again it is individual kidneys, i.e., the particular tokens of the natural kind that engage in causal processes such as ontogeny. However, ontogeny, or descent with modification, requires plasticity if evolution is to occur. In order for this to be possible, an adequately weak notion of a natural kind must therefore be invoked such as the “homeostatic property cluster natural kind” proposed by Boyd (1991, 1999).

Common evolutionary origin can be the (essential: LaPorte 2004) property that marks out biological natural kinds, like taxa or homologs, but tigers and their parts, such as their kidneys and their parts, such as kidney tubules, share other properties as well. For example, tigers share a genetic constitution, which they transmit—more or less reliably—to offspring as they engage in the causal process reproduction. Kidneys engage in the causal process of excretion, a function that changed in some regards as renates evolved from water to land. Tokens of natural kinds which in virtue of their properties engage in developmental and physiological processes must be capable of plasticity if evolution is to occur. On the other hand, variation must not be so rampant as to disrupt ontogeny or physiological function. The clustering of properties in a variable and partially overlapping pattern that characterizes homeostatic property cluster natural kinds is believed to be effected by homeostatic mechanisms, which are
themselves plastic and capable of variation and change (West-Eberhard 2003). “Because the clustering in the world that defines such a kind can be an ongoing process, the properties in the cluster can sometimes vary over time, and the kind’s boundaries can be historically delimited if the clustering is historically delimited” (Keller et al. 2003 p 105). With genealogy itself being a homeostatic mechanism of property cluster natural kinds (Boyd 1999), the latter can also be conceived of as historical kinds (Sterelny 1994 p 11), a perspective that accommodates species as well as homologs.

6.3 Similarity, homology, and congruence

The relation of homology is a theoretical concept because it is based on common evolutionary descent. Since common evolutionary descent cannot be observed, it must be inferred from observation. Traditionally, biologists will take some sort of similarity relation to be indicative of common ancestry (Rieppel and Kearney 2002). Indeed, under the paradigm of evolution, homology is frequently defined as “similarity due to common descent” (West-Eberhard 2003 p 485).

However, similarity is a highly loaded concept. Goodman (1972 p 437) called similarity “a pretender, an imposter, a quack,” whereas Hull (1999 p 35) found it “unanalyzed, perhaps unanalyzable.” “As philosophers have long recognized, similarity without theory is empty” (Sober 1984 p 336; see also Ruse 1988 p 60; Dupré 1993 p 45). So “similarity” is taken to be a primitive concept that cannot be further defined, and yet it is hardly possible to “imagine a more familiar or fundamental notion than this, or a notion more ubiquitous in its application” (Quine 1994 p 42).

In the face of these problems, contemporary systematics has experienced the revival of an outdated empiricism (Sneath and Sokal 1973) that was thought to have been put to rest long ago. It consists in a purely instrumental–algorithmic approach to homology in which the array of all phylogenetic hypotheses possible for N number of terminal taxa is used as an instrument to generate statements of putative homology. As argued by Hárlin (1999 p 497), “too much emphasis is put on particular characters” given the “logical priority of the tree over the characters.” Similarity as a tool of systematics is declared bankrupt, and theory is eschewed on grounds of lack of positive knowledge. Critical character analysis is rejected as a “disturbing trend toward data selectivity” (O’Leary et al. 2003 p 861) by proponents of the “total evidence approach,” who cite Kluge (1997) in support of the notion that inclusion of all data, including all “published data,” results in a stronger test of homology and phylogenetic relationships (O’Leary et al. 2003 p 862). But to eschew theory in favor of an instrumentalist–algorithmic approach
to character analysis does not mean to take an atheoretical stance, and as pointed out by Ruse (1988 p 60):

- As soon as one starts breaking organisms into parts, one must bring in theory . . .
  Take two bears, one white and one brown. Do they differ in one feature, or does one take each hair separately . . . The point is whether someone who explicitly eschews . . . theory has the right to combine all the hairs into one feature.

  Proponents of the “total evidence” approach (Kluge 1989) argue, “there is no one operation for determining character states in this system—it can be anything that leads to the testable hypothesis of synapomorphy” (Kluge 2003a p 356; emphasis added). Even more drastic yet more sophisticated is Griffith’s (1999 p 225; emphasis added) assertion that

- cladistic analysis can proceed from a list of arbitrary measurements by looking for congruence among the evolutionary trees produced by different measurements . . . thus ‘bootstrapping’ itself into a reliable character set.

  Such a data set, “holding itself up by its bootstraps” Audi (2003 p 187), has been called the result of “phenetic cladistics: elegant analyses with many sources of error” (Wägele 2004 p 109). “We might just [as well] stop tugging at our bootstraps altogether” (Quine 2001 p 457).

  Contemporary systematists see homology assessment as a two-step procedure: the conjecture of homology (primary homology statements \textit{sensu} dePinna 1991), and the test of those on the basis of congruence (yielding secondary homology statements \textit{sensu} dePinna 1991). With a misguided appeal to Popper’s philosophy of science (Kluge 2003b, 2004), the proponents of the phenetic approach to cladistics consider the contextual origin of primary homology statements (conjectures of synapomorphies in Kluge 2003a) irrelevant, \textit{as long as} there is a method to test those statements. The test of choice is not Popperian, however, but built on congruence. The issue is not whether an observation statement is accepted as falsifying the theory from which its negation was deduced, as is the case in Popper’s hypothetico-deductivism (Rieppel 2003a, 2004b). Instead, the issue is whether character statements cohere to a degree that seems sufficient for the (provisional) acceptance of a phylogenetic hypothesis.

  Patterson (1982 p 74) considered Wilson’s (1965) consistency test for phylogenies “a more rigorous formulation of my congruence testing.” The work done by the test of congruence is to maximize the consistency of all available data in marking out an enaptic (inclusive) hierarchy. In a “pattern cladist” approach, Patterson (1982) took characters to mark out sets and analyzed the consistency of their distribution in terms of mutual inclusion, mutual exclusion, or overlap of the sets the character statements define. The same logic underlies “Hennig
argumentation” (Hennig 1966), ultimately based on the “inclusion/exclusion principle” (Wiley et al. 1991 p 45). Accordingly, the test of congruence is based on logic as it tests for coherence versus contradiction of character statements, but logic has a linguistic foundation (Soames 2003 p 136). Coherence and contradiction are logical relations that obtain between sentences only and the propositions they express, not between organisms and their parts. Kidneys and notochords cannot cohere or contradict each other, only statements about kidneys or notochords can. The test of congruence therefore does not test for descriptive accuracy, causal relevance of character statements, or the like. It only tests for coherence (consistency relative to a hierarchy of sets within sets, or, in the present analysis, kinds within kinds) of character statements. That is why phenetic cladistics is prone to many sources of error. If the contextual origin of conjectures of homology (primary statements of homology) were indeed irrelevant, and if the test of congruence were indeed sufficient for phylogeny reconstruction, there would be no theoretical basis on which to reject the purely operational “punch-card approach” (Sneath and Sokal 1973, Figure 3.1) to the automatic scanning of characters. If congruence and nothing else is used in a test of character statements, then the support for a phylogenetic hypothesis derives exclusively from the mutual support of the coherent character statements, without consideration of how those character statements do or do not refer (apply) to the organisms under analysis. The individual character statements, and with them the phylogenetic hypothesis they putatively support, potentially remain hanging in the air. Haack (1998 p 27) found such inference to fall victim to the “drunken sailor argument” that invokes the picture of two drunken sailors who believe they can mutually support each other by standing back to back when both stand on nothing.

Of course there can be no doubt that character congruence, i.e., the coherence of character statements relative to a hierarchy, is a necessary condition for phylogeny reconstruction. Incoherent talk about the world makes no sense, not in phylogenetics, nor in any other domain of discourse. But the mere coherence of character statements is not also a sufficient condition for phylogeny reconstruction. If they are not to be left hanging in the air, character statements must somehow be grounded in the organisms under analysis, i.e., rooted in causal theories of inheritance, development, and/or function. Homologies are natural kinds only if their tokens (at least potentially) take part in causal processes. To thoroughly investigate the genetic, developmental, even functional background of each character used in phylogeny reconstruction is beyond practical reach, however. Homology is a theoretical relation that has to be inferred from observation, but observation cannot proceed meaningfully without theory and outside the context of background knowledge (Hanson 1961; Haack 1998). Quite simply
put: to be relevant to a theory, the predicate deployed by an observation statement must have a theoretical counterpart in the theory (a set of theoretical sentences) to which the observation statement is meant to relate to (Körner 1970; Mahner and Bunge 1997). Theory and background knowledge will therefore have to be brought to bear on observations that result in the formulation of primary homology statements. Even if the distinction is unsharp and sometimes difficult to draw, this is how relevant evidence is generally distinguished from total evidence (Haack 1998). More specifically, a method is required that will allow to ground primary homology statements at least approximately, and certainly defeasibly (the hypothesis of primary homology may be wrong) in causal theories of inheritance and development. This method consists in the application of the “operational criteria of homology,” such as topology and connectivity (Remane 1952; Riedl 1977 showed that the additional operational criteria of homology formulated by Remane 1952 ultimately all reduce to topology and connectivity).

Quine (1994 p 43; emphasis added) found that “there is something logically repugnant about” similarity in its primitive, innate, unanalyzed, and unanalyzable sense (Goodman 1972; Hull 1999). But science sheds this kind of similarity as it matures. Quine (1994 p 53) used chemistry as an example of a maturing branch of science, in which “comparative similarity of the sort that matters for chemistry can be stated . . . in terms of chemical composition. Molecules will be said to match if they contain atoms of the same elements in the same topological combinations.” The causal efficacy of chemical kinds is thus explained as a consequence of the topological relationships of their constituent elements. This is exactly the kind of similarity that also matters for the relation of homology. Systematists do not look for any kind of similarity, but for a special kind that it is established on the basis of operational criteria of homology, i.e., the relative topological position and connectivity of constituent parts of an organism (both morphological and molecular) in their temporal (ontogenetic) and spatial (ontogenetic, molecular) manifestations. Topology and connectivity yield the special kind of similarity that delivers promissory notes for potential homology. Same-ness or (historical) “identity” has been invoked for homologs that carry the same name, but there is no “perceptual sameness” (Kluge 2003b p 236, and n. 12) in a comparison of the lower jaw of a shark and the outermost ear-ossicle of a mammal. However, there is perceptional topological correspondence (during early ontogenetic stages) that justifies the conjecture of homology (Reichert 1837).

The operational criteria of homology can be compared to “correspondence rules” (Rieppel 2003b) which, stripped of their positivist background, mean nothing more than either an experimental setup or an observational procedure
Mahner and Bunge (1997) use the broadly equivalent term “indicator hypothesis” which, in the present context, would be hypotheses that do not tell us what homology is, but instead guide us how to “look for” potential homology. The operational criteria of homology have empirically been found to be eminently successful in the reconstruction of the tree of life (Remane 1952; Riedl 1977), which is why it may be assumed that they provide a (defeasible, i.e., potentially mistaken) proxy for the causal grounding of hypotheses of homology in theories of inheritance, development, and evolution. In Boyd’s (1991, 1999) terms, the use of the operational criteria of homology seems to be well aligned with the causal structure of the world, at least to some degree, and defeasibly so (Rieppel and Kearney 2002). The use of operational criteria of homology cannot, therefore, be theory free. They do not establish a purely “operational” link that maps a theoretical statement of homology on to an observational statement of topological correspondence of parts. The theoretical background that justifies the use of operational criteria of homology is the recognition that topology and connectivity are expressed in development, and that evolutionary transformation of morphology occurs through the transformation of development (see further discussion later). A similar adherence to correspondence rules is known in molecular systematics: “Alignment of sequences requires explicit and objective rules if inferences of positional homology are to be robust” (Hillis 1994 p 349; but see Wheeler 1998).

6.4 Development and homology

Homologs share a common evolutionary origin, but “neither traits nor representations of traits are transmitted to offspring. Instead, they are made—reconstructed—in development” (Oyama et al. 2001 p 2). Both development and evolution can be conceived of as a “process of construction and reconstruction in which heterogeneous resources are contingently but more or less reliably reassembled for each life cycle” (Oyama et al. 2001 p 1). Development results in pattern formation, an “activity by which embryonic cells form [spatially] ordered arrangements of differentiated tissues” (Gilbert 1988 p 589), and comparative morphology analyzes these patterns in terms of topology and connectivity. Raff and Sly (2000 p 102) noted that developmental modules “occupy specific physical sites within the embryo,” and “exhibit varying degrees of connectivity to other modules within the embryo.” This is the juncture at which the operational criteria of homology find their partial, and defeasible, causal grounding in the process of development. It is for these reasons that developmental modules, themselves natural kinds (Wagner 1996, 2001; Brandon 1999; Rieppel 2004c), have been
identified as the “traditional units for claims about homology” (Winther 2001 p 117). However, the use of ontogeny to causally ground homology statements is riddled with difficulties.

For Darwin (1859 p 449), “… community in embryonic structure reveals community of descent. It will reveal this community of descent, however much the structure of the adult may have been modified and obscured.” However, in the fourth edition of the Origin (1866 p 312; see Peckham 1959), Darwin added: “… community in embryonic structure reveals community of descent; but dissimilarity in embryonic development does not prove discontinuity of descent.” The reason is that structures considered homologs may share strikingly different developmental trajectories. A simple and classic example is the generally accepted homology of the vertebrate brain in spite of the fact that the neural plate delaminates, rather than invaginates, in teleosts. Hall (1995) presented a review of the role of ontogeny as a criterion of homology, concluding that “homology can no longer retain its historical links to shared embryonic development,” for “there are so many examples of homologous structures arising from nonhomologous developmental processes” (Hall 1995 p 8; see also Rieppel 1993; Hall 1994; Rieppel and Kearney 2002). But just as potential homologs can develop along different ontogenetic trajectories, so can a similar developmental background generate very distinct morphologies: “The transcription factors ‘distal-less,’ ‘engrailed,’ and ‘orthodenticle’ each have orthologs involved in patterning very different structural features in different metazoan taxa” (Mindell and Meyer 2001 p 435). Similarly, Raff (1996 p 352) found it surprising “that both genes and principles of appendage development are shared between two phyla,” i.e., arthropods (Drosophila) and vertebrates (tetrapods). As summarized by Wagner (1994 p 275), organs with the same structural organization (structurally identical body parts) may have different developmental pathways, may use different genetic information for their development, and may not share a common phylogenetic origin.

Developmental biologists therefore recognize different concepts of homology, of which the one discussed in the preceding section—the phylogenetic or “taxic” concept of homology—is only one. In addition, there is the “morphological homology concept” that uses “structural identity for its definition,” and the “biological homology concept,” which is based on “shared developmental constraints” (Wagner 1994 p 174; Roth 1984 emphasized shared developmental pathways instead). According to the latter concept, “structures from two individuals or from the same individual are homologous if they share a set of developmental constraints, caused by locally acting self-regulatory mechanisms of organ differentiation. These structures are thus developmentally individualized parts of the phenotype” (Wagner 1994 p 275; see also Wagner 1989).
In contrast, West-Eberhard (2003 p 486) distinguished what she called “broad-sense homology” (corresponding to “biological homology”) from “cladistic homology.” In contrast to cladistic homology, broad-sense homology allows for parallelisms (see the discussion above on the problem of an empirical distinction of parallelisms from taxic homology), and the recurrence of features previously lost in phylogeny. As such, broad-sense homology includes cladistic homology as a subset, the two concepts in fact representing “complementary approaches to understanding the evolution and stability of structure” (West-Eberhard 2003 p 488; on the issue of complementarity see the discussion later). Indeed, statements of biological homology and statements of phylogenetic (taxic, cladistic) homology may be expected to be congruent if the developmental mechanisms underlying the corresponding structures are so complex that their repeated evolution would seem very unlikely (Shubin 1994 p 206). However, because of the problems outlined previously, “there is no rigorous way in which biological homology concepts can be used to distinguish between phylogenetic homology and homoplasy” (Shubin 1994 p 206). It is for these reasons that comparative studies of development “can be used to trace homology, but developmental differences do not negate it” (West-Eberhard 2003 p 496). Similarity of gene expression patterns and developmental pathways as captured by biological homology may support hypotheses of taxic homology but not the other way around (Rieppel 2004c).

6.5 Partial homology or partial reference?

If true that development is a “process of construction and reconstruction in which heterogeneous resources are contingently but more or less reliably reassembled for each life cycle” (Oyama et al. 2001 p 1), a situation might arise in which a developmental biologist would want to invoke a concept of partial homology. The concept of modular development (Raff 1996; West-Eberhard 2003; for a review and references see Rieppel 2004c) builds on connectivity yet dissociability of developmental modules. If developmental modules are dissociable, they can potentially “be reorganized somewhat independently of each other” (West-Eberhard 2003 p 60), thus providing the resources for reassembly of traits derived from heterogenous resources in descendant life cycles. Such “mosaic development” results in heterochrony, heterotopy, and other effects (Raff 1996) that led West-Eberhard (2003 p 60) to speak of homology as “not an all-or-nothing phenomenon but rather a continuum of more or less similarity due to common ancestry.” This conclusion, startling from a systematist’s point of view, would
seem to be supported by Raff’s (1996) review of appendage development in *Drosophila* and tetrapods. Why not speak of partial homology of appendages in those widely separated lineages in which “appendages have a deep underlying and (prior to the findings of developmental genetics) completely unexpected homology” (Raff 1996 p 353; see also Shubin et al. 1997; Gilbert and Bolker 2001)? Very basal building blocks are used to develop vastly different structures. But is it true that through such mosaic development, “evolution makes a mess of homology” (West-Eberhard 2003 p 497)? Such a conclusion seems subject to a naturalistic fallacy. Homology is a theoretical concept. It may, indeed, be the case that our theoretical concepts are somewhat messy, but this is not because of evolution. The evolutionary process just unfolds the way it does, and this may be a way that is difficult to capture conceptually.

The call for partial homology can have two sources: the heterogeneous combination of ancestral resources in descendant life cycles as outlined previously, or gradual and continuous morphological change as in Sattler’s (1990, 1996, and references therein) “continuum morphology,” which essentially reduces structure(s) to process(es). Although at odds with cladistics, Weston (2000 p 141) considered it an avenue toward holism if partial homology was fitted as a distance measure on a tree. Why this appeal to holism?

The corollary of “continuum morphology” is that it “acknowledges gradations between typical structures . . . . From this point of view, homology is a matter of degree” (Sattler 1996 p 577). The tension identified by Sattler (1990, 1996) between “typical structures” and the “continuity of developmental processes” broadly corresponds to the tension between “evolution and stability of structure” that was used by West-Eberhard (2003 p 488) in support of her claim for complementarity. Indeed, the contrast between pattern and process can quite generally be conceptualized in terms of complementarity (Rieppel 1988), although this may in turn result in some tension with scientific realism that adheres to ontological monism. Ontological monism holds that there is one, and only one, way to carve nature at its joints, i.e., that particles and waves are not two different kinds of light but rather a reflection of our imperfect understanding of light. Accordingly, McMullin (2002 p 252) argued that complementarity invoked in physics does not also invoke an ontological dualism, but rather points to the issue of partial reference of the terms deployed in complementary theories. The same seems true for biology.

The discussion of partial homology in terms of morphological stasis versus continuity of developmental change mirrors the paradoxical discussion of “species” as spatio-temporally delimited chunks of a genealogical continuum. With respect to species, Hey (2001 p 168) found that “systematists and
evolutionary biologists have both placed incommensurable demands on a word,” in which the word “species” is supposed to function in the context of pattern as well as process analysis (Hull 1997), and the same is true of homology. But again: “a tendency for different perspectives by different biologists [must not] be confused with different kinds of reality” (Hey 2001 p 150). Indeed, if species transformation is a gradual process, any species concept will be subject to the “Sorites Paradox” (Rieppel 2003b): take a heap of sand and remove grains one by one—when would one stop calling it a “heap”? Under the paradigm of gradualism, species boundaries will be unsharp, fuzzy, no matter which concept is deployed in their delineation (Hey 2001). The same is true of homology in cases in which morphological transformation (developmental and phylogenetic) is a gradual process. There is, however, a conceptualization of species that specifically allows for such fuzziness, which is that of homeostatic property cluster natural kinds (Boyd 1999; see also Griffiths 1999; Wilson 1999; Keller et al. 2003). The same concept can be applied to homologs, as was discussed previously (Rieppel 2004c). The conclusion is not that evolution makes a mess of homology, but that it is the names associated with the natural kind terms (predicates) we deploy in statements of homology that may have imprecise, or even only partial, reference (the terms apply only imprecisely, or partially, to the organisms under analysis).

A second issue to consider in relation to the concept of partial homology is the fact that natural kinds, such as taxa, or homologs, come in hierarchies and thus raise the qua-problem for natural kind terms as discussed previously (Devitt and Sterelny 1999). The statement “bird wings and bat wings are homologous” makes little sense unless it is tied to a conditional phrase. The same is true of the statement “arthropod and tetrapod appendages are partially homologous,” unless the question is raised in which sense they are homologous, partially or not. The concept of partial homology may reflect a tendency of developmental biologists to use broad-sense homology independent of a hierarchical conception of development. If the sense of partial homology in this example relates to certain gene expression patterns (a “similar genetic cascade”) (Shubin et al. 1997 p 646), then the homology relation exists not at the level of appendages, but at the level of genes, which ties the homology relation to its proper hierarchical level. Gilbert and Bolker (2001 p 447) speak of such gene-level homology as “deep homology,” for insect “legs” and vertebrate “legs” obviously cannot be homologous as appendages, because “phylogenetically intermediate taxa (particularly basal chordates) do not possess comparable structures” (Shubin et al. 1997 p 645). However, Gilbert and Bolker (2001 p 449) added a note of caution to this tale of wings and legs. Applying the “small toolbox argument” to developmental processes in
the name of parsimony, they draw attention to the fact that genetic resources that regulate basal (early) patterning processes in development are limited, for which reason convergent gene expression patterns are difficult to rule out. For example, much of the “toolbox” that is involved in early limb development is also involved in the early development of vertebrate teeth.

6.6 Taxic versus the transformational approach to homology

The phylogenetic literature that deals with species, taxa, as well as with homologs, is replete with dismissals of taxa, or homologs, as natural kinds, for these are considered abstract entities, like sets, or classes (Hull 1999). The same is true of properties (attributes), which are dismissed as universals that cannot be instantiated by evolutionary entities (Grant and Kluge 2004). Hey (2001 p 153) for example dismisses property cluster kinds as polythetic classes, where “a polythetic class is just a category in which the members need only meet some, not all, of the membership criteria.” But as emphasized previously: for property cluster kinds (as well as for other kinds) to be natural requires that their properties are relevant to causal processes, i.e., that tokens of kinds take part in causal processes by virtue of their properties (Sober 1981; Boyd 1999; Shoemaker 2003; LaPorte 2004; Lipton 2004).

Homologs (Grant and Kluge 2004), as well as species (Hull 1999), have been considered to be particulars (individuals). This move was motivated by a certain reading of Hennig (1950, 1966), which found him to have replaced “intensional” with “extensional” thinking in systematics (Dupuis 1984). Such reading of Hennig has led to the assertion that systematics must rely on “ostension” and “extensionality” (Kluge 2003a). The meaning of extensionality as used in this context remains obscure (Dupuis 1984 p 13: “Hennigian taxonomy is extensional since, for appraisal of each attribute, it requires an extensive consideration of various objects”), whereas the relation of ostension is more easily understandable. In the simplest case, ostension is the relation of “pointing at” an object in order to establish that object as the referent of a proper name, or of a sentence of the subject–predicate structure (Fx). But for Grant and Kluge (2004), it is not objects and their properties that serve as homologs. Instead, “only the transformation from one character state to another, a → a’, constitutes evidence in phylogenetic inference” (Grant and Kluge 2004 p 25). If only transformation events constitute evidence, and if systematics is to be ostensional, then systematists would have to be able to “point at” such transformation events.
The collapse of a bridge or the burning of a house are events that witnesses can point at, but the transformation events that are of interest to systematists are events of the past. What is required, therefore, is identification of character states and inference of their transformation. “However, character state transformation has always been treated primarily as a metaphor … Furtherermore, character states themselves can be seen as manifestations of the transformational metaphor” (Weston 2000 p 135). In this quote, I would replace the term “metaphor” with that of “concept,” for as convincingly argued by Hanson (1961), perception itself entails a conceptual component (Rieppel 2004a). As noted earlier, the mere pointing at a rabbit and the utterance of “gavagai” by a native speaker does not tell the English speaking audience what the native speaker means by gavagai: a rabbit, an undetached rabbit-part, or a rodent (Quine 1964)? It seems impossible to meaningfully talk about the world without concepts (Luntley 1999).

A transformation series of character states purported to be homologous does not result from mere ostension but from character conceptualization (“transformation series analysis . . . begins with the construction of an initial transformation series”: Kitching et al. 1998 p 218; my emphasis). Hennig (1966 p 94) was very clear on this issue: “the belonging of characters to a phylogenetic transformation series . . . cannot be directly determined.” To solve the problem, Hennig (1966 p 94) turned to an account (in Cain and Harrison 1958 pp 86–88) of J.H. Woodger’s analysis of morphological comparison in the language of logical positivism (Rieppel 2003b), which “to that extent is exact” (Hennig 1966 p 94). According to Woodger (Cain and Harrison 1958), morphological comparison individuates parts of organisms in terms of their relation, and compares them in terms of their properties. The description of properties of, and relations between, objects are the cornerstones of the positivist philosopher Rudolf Carnap’s “construction theory,” i.e., the theory of how science reconstructs the logical structure of the world (Mayhall 2002). As argued earlier, the same theoretical background underlies Hennig’s (1957, 1966) conceptualization of the cladogram (Rieppel 2003b). There is no need to look back on Carnap, Woodger, or even Hennig, however, to understand that the identification of characters, character states, and transformation series entails a conceptual component (Hanson’s (1961) work was, after all, a stab at the positivists’ adherence to something akin to “simple” observation). In his talk announcing his own transformation, Farris (Mitter 1980 p 188; see also Dupuis 1984 p 16) asserted that “morphologists do not sample characters, they synthesize them.” If “extensional” systematics must be based on ostension, but if it admits only character transformation as evidence, then the argument boils down to the claim that systematists must be able to “point at”
concepts. This conclusion merely shows that such arguments confound concepts with objects (Mahner and Bunge 1997).

The discussion of transformation series reflects back on the “transformational” versus “taxic” approach to homology that was hinted at by West-Eberhard (2003) in her distinction of broad-sense versus cladistic homology. The essence of this debate (that started with Patterson 1982) is that the transformational approach allows homology to encompass both symplesiomorphy and synapomorphy, whereas the taxic approach requires homology to be synonymous with synapomorphy (it requires a statement of homology to be coextensive with a statement of synapomorphy). Wiesemüller et al. (2003 p 89) consider the taxic approach as too coarse grained because it blurs the distinction of plesiomorphy and apomorphy, in addition to the fact that the concept of homology cannot easily be applied to “absence”-characters. The latter problem was (arguably) “solved” semantically: snakes do not have “no legs,” instead they have “modified legs,” i.e., “lost legs” (Platnick 1978; see the discussion of the deduction of different meanings from different premises in Rieppel 2004b p 79). The distinction of homology from symplesiomorphy and synapomorphy on the other hand is related to the *qua*-problem. “Bird wings and bat wings are homologous” violates the requirement for coextensionality of statements of homology and of synapomorphy because it implies a symplesiomorphy: birds and bats share tetrapod (fore)limbs, not wings. Patterson’s (1982) goal simply was to remove ambiguity, and render statements of homology testable by congruence, in claiming that homology statements should always be assessed as (*qua*) statements of synapomorphy—since what is a symplesiomorphy at one level (jaws of amniotes) becomes a synapomorphy at a more inclusive level (jaws of gnathostomes). Interesting evolutionary talk about a comparison of bird wings with bat wings would be talk about convergence, but then bird wings and bat wings could not be homologous.

### 6.7 Conclusions

Homology is one of two perennially discussed topics in comparative biology—the other is species. The two discussions show many parallels, as indicated previously: proper names versus general names, individuals versus classes, sets, or kinds. To turn homologs into individuals and anatomical (or molecular) terms into proper names (Grant and Kluge 2004) is patterned on the argument that species are individuals (e.g. Hull 1999). This latter argument has received a lot of attention from evolutionary biologists, who largely missed an important
part of its theoretical foundation. In his defense of the argument from a philosophical point of view, Hull (1976 p 179, n. 4) drew attention to the semantic behavior of species names in evolutionary theory, which in his analysis corresponds to the semantic behavior of proper names as “rigid designators” (Kripke 2002). Such behavior of proper names is tied to a specific theory of reference for proper names, i.e., the “historical,” “causal,” or “direct” theory of reference (Hull 1976 p 179, n. 4; see also Hull 1988). These are all rather technical issues that need not be reviewed here; there is also no need to deliver a verdict on the ontological status of species here. The important point is that authors who want to use—in an evolutionary context—the “names” that refer to “the same organ in different animals under every variety of form and function” as proper names will need to worry about those technicalities but have not done so far.

In the present context, homology is conceptualized in terms of natural kind term semantics, and the names associated with natural kinds can be general names or singular terms (Soames 2002). Kripke (2002) himself already expanded his theories to also apply to natural kind terms, such as “tiger”, “water,” or “gold,” but as noted by Devitt and Sterelny (1999), the use of such terms — at least in the case of biological natural kinds — at some level involves some descriptive account (for Kripke 2002, a descriptive account may help to fix reference, but does not determine reference, of proper names or natural kind terms). This means that the use of names (associated with natural kind terms) to refer to “the same organ in different animals under every variety of form and function” must be tied to a conditional phrase that specifies the hierarchical level at which the use of that name gains some cash value in terms of marking out monophyletic groups. This in turn means that phylogeny reconstruction cannot be a matter of mere extensionality and ostension (Kluge 2003a, b; Grant and Kluge 2004), but requires a conceptual, i.e., a theoretical framework. There is no immediate access to objective reality, but this only means that careful phylogenetic analysis will require at least an attempt to causally ground hypotheses of homology, proximally in criteria of topology and connectivity, ultimately in the theories of inheritance, development, and evolution.

7 Taphonomic and Diagenetic Processes

Gisela Grupe

Abstract

The recycling of matter within an ecosystem is a fundamental process and therefore, fossilization of a body or its parts is always the exception to the rule. The transition of organic remains from the biosphere to the lithosphere (= taphonomy) comprises the successive steps of necrology, biostratinomy, burial, and diagenesis. Focusing on the taphonomy of vertebrate skeletons, fossil types, and the main processes leading to preservation and/or destruction of a dead body and how these are intertwined, are introduced. All in all, fossilization is not a random process. Almost all of the first-order changes a dead body is subject to prior to fossilization may lead to alterations in size and shape of a skeletal part, which might be mistaken for artificial manipulations (pseudoartifacts). Taphonomic processes without doubt lead to a stepwise loss of information about the formerly living being. Today, methodological progress especially in the field of archeometry permits the evaluation of a variety of lifetime parameters. However, deep insights into taphonomic, especially diagenetic, processes are the indispensable prerequisites.

7.1 Introduction

The recycling of matter is one of the fundamental processes of life. Fossils, on the other hand, are evidence for the possibility that either complete organisms or their parts may be transferred from the biosphere to the lithosphere with preservation of morphological and even biochemical features. With regard to the various biogeochemical cycles, which are characteristic for ecosystems, fossilization is necessarily the exception to the rule.

7.2 Taphonomy

Taphonomy is the paleontological subdiscipline that unravels the processes an organism is subject to from its death until its recovery (Figure 7.1). The term
“taphonomy” was introduced by the Russian paleontologist Efremov (1940) as the study of the transition of organic remains from the biosphere to the lithosphere, whereby the etymological origin of the term from the Greek taphos = tomb implies the necessity that the dead body or its parts become buried sooner or later after death (note the origin of the term “fossil” from the Latin word fossilis = excavated, related to fodere = to dig, or effodere = to excavate). Carcasses that remain on the surface usually do not have a chance to turn into a fossil and will instead undergo complete decomposition (Miller 1975; Gill-King 1997). The preserved fossil record is greatly biased toward organisms, which have durable, hard parts like mineralized tissues, and to those organisms which occur in large numbers, hence with high-population density. Fossilization therefore is a nonrandom process.

### 7.2.1 Taphonomic analysis

The first step of taphonomic analysis comprises necrology, the actual death of an organism. While most animals die in toto, entire plants frequently do not but rather shed parts like leaves or pollen, which may fossilize. After death, biostratinomy is responsible for the further condition of a fossil prior to its burial and includes processes like disarticulation (by scavengers or intended...
dismemberment by butchering), weathering and trampling, gnawing and scavenging, root etching, and even heat exposure (accidental or intended). Moreover, the body or its parts can be subject to transport by wind, water, animals, or simply to gravity, when it is exposed somewhere uphill. As a consequence, most fossils will be removed from their original context and the place of recovery will differ from the place of individual death. In the case of hominids, this situation changed after humans started to intentionally bury the dead. Finally, the bodily remains become buried, and diagenesis sets in. Diagenetic processes involve all interactions of the dead body or its parts with the surrounding sediment, which either end up in the complete disintegration and dissolution of the body or in its lithification. “Diagenesis” is a term derived from the Earth Sciences and refers to the biological, chemical, and physical changes that take place in sediments after their deposition and that end up in lithification.

In this narrow sense, diagenesis also applies to fossils. Today, this term is frequently used in its broader sense and is synonymous with “decomposition,” and refers also to subfossil and prehistoric bones and to finds of forensic relevance. The state of preservation of a dead tissue will give clues to burial conditions, burial practices, and sometimes even to antemortem conditions such as cause of death or existing diseases. Antemortem injury or infection, or any pathology which causes tissue breakdown during life is likely to accelerate decomposition. Even after lithification, fossils may show up on the surface due to erosion, where they are again subject to weathering and trampling.

Taken together, the taphonomic processes lead to a stepwise loss of information about the formerly living being, or at least to a decline of the integrity of the information through the many ways that the evidence can be altered (Reitz and Wing 1999). However, the statement by Shipman (1981a, p 3) “in short, through death most evidence of the interesting information about animals—what they look like, what they eat, how they move, where they live, and so on—is lost” now requires, more than 20 years later, some revision: methodological progress, particularly in terms of archeometry, permits the evaluation of several of the above-mentioned parameters, including genetic relationships in cases of preserved DNA (this book, Chapters 9, 17, and 20). But it becomes also clear that any research on the molecular or crystal level necessitates deeper insights into taphonomic, especially diagenetic, processes. Thus the early statement by Weigelt (1927) that taphonomy and disintegration will give clues to the paleoenvironment in which the fossils were buried still holds today, and taphonomy has now become an integral area of paleoenvironmental research.

Nonetheless, taphonomy has largely changed from a paleontological subdiscipline into a scientific field of its own, where research mostly focuses on either biostratinomy or diagenesis (Domínguez-Rodrigo et al. 2003). Since the 1980s,
several books covering this topic provide proof of the development of this field of research (Behrensmeyer and Hill 1980; Binford 1981; Brain 1981; Shipman 1981a; Allison and Briggs 1991; Donovan 1991; Lyman 1994; Martin 1999). Taphonomic analyses are also of great importance for archeozoology, since animal bone deposits are usually the remainders of kill or butchering sites, or village or home-based refuse. The animal bones are characterized by several kinds of manipulation before being deposited, and the individual animals have been transferred from the living community into the archeological deposit (Reitz and Wing 1999).

With regard to the aims and scopes of this handbook, this chapter concentrates on the taphonomic and diagenetic processes acting on the vertebrate skeleton, since the mineralized parts of a body have a higher probability of turning into a fossil than soft tissues. However, depending on the mode of preservation, the latter may also leave their traces.

### 7.3 Modes of preservation

Several modes of preservation exist, which are explained in the following sections.

#### 7.3.1 Mineralization

This involves organic matter and necessitates exposure to water. Organic matter is gradually infiltrated and replaced by minerals derived from the watery environment, and mineralization results in the preservation of the shape of the organic component, sometimes down to individual cells (Nicholson 2001).

#### 7.3.2 Carbonization

This results from heat and/or pressure, which removes all volatile organic components and leaves nothing but a carbon layer. This way, coal is generated from dead plant tissue.

#### 7.3.3 Permineralization or petrification

This is the result of the infiltration of natural hollow spaces of plant tissue, such as the xylem of woods, by infiltration and precipitation of exogenous minerals. If this exogenous material is made out of silica, wood will petrify.
7.3.4 Recrystallization

This is a process during which original mineral crystals change in size and shape, mediated by temperature and pressure. The chemical composition, however, is not changed, as in the case of the change of aragonite (CaCO₃, rhombic crystals) into its more stable form, calcite (CaCO₃, trigonal crystals). After death, mineralized tissues may be subjects of a spontaneous rearrangement of the crystalline matrix (Henderson 1987). Since the crystals change in both size and shape, morphological details will not be preserved, and even destruction may occur.

7.3.5 Heteroionic substitution or replacement

It is a mode of preservation, whereby the mineralized components of a body are substituted molecule-by-molecule, or ion-by-ion, with exogenous material. This process also takes a long time because the original mineral has to first dissolve before it can be replaced by exogenous precipitates, like silica, which are less soluble. Morphological details will be preserved, contrary to recrystallization; hence substitution may lead to a “perfect” fossilized skeletal part.

7.3.6 Molds and casts (authigenic preservation)

These are special fossil types wherein a body part gets trapped into sediments which harden, while the original bodily tissue (mostly bone or shell) dissolves. Thus, a void is produced within the sediment, and its negative relief can preserve the impression of the former body part left on the still soft sediment. Hardening sediment, producing a cast (with a positive relief), may again infiltrate this void. It is also possible that sediment infiltrates a shell or a hollow space of a skeleton, e.g., the brain case, and hardens while the shell or bone dissolves. The resulting mold will also have a positive relief as in the case of the brain cast of the Taung child. Under special circumstances, bodies may be preserved unaltered, like insects trapped into amber. A special category however concerns.

7.3.7 Trace fossils

These can be defined as “modifications resulting from the activity of living organisms on and in substrates.” Trace fossils include gnawing and butchering
marks on bones (feeding traces, see later), but mainly concern visible tracks of a no longer visible body (or its parts), like fossil rodent burrows, sleeping pits of hibernating cave bears, or the so-called “bear polish,” a gloss on stones resulting from the polishing action of bears fur in narrow cave passages (for review, see Gautier 1993). The most famous such fossil in the paleoanthropological record is the preservation of the australopithecine footprints from Laetoli. Such impressions will be preserved when they are buried quickly. Rapid burial is less uncommon than sometimes assumed, since not only volcanic ash eruptions, but also storms, floods, or landslides may cause sedimentation within hours.

In this sense, fossilized feces called coprolites (from the Greek copros = dung and lithos = stone) can also be included into this highly variable group of trace fossils because coprolites are the result of the metabolic transformation of living organisms (edible plants and animals) into feces that subsequently fossilized. Coprolites from many animal species including dinosaurs have been recovered and they are mostly preserved by mineralization after rapid burial (Hollocher et al. 2001, Chin et al. 2003). However, very old coprolites are not easily identified in terms of their origin, and this holds especially for the fossilized feces of omnivores. Coprolites suggested to be of hominid origin were removed from the Australopithecus africanus site at the Olduvai Gorge, from the Homo erectus site at Terra Amata, and from a Homo neanderthalensis site at Lazaret. In none of these cases could their hominid origin be confirmed by conventional coprolite identification methods (cf. Trevor-Deutsch and Bryant 1978).

### 7.3.8 Bog bodies

These are not fossils in the narrow sense since they are not lithified. However, the special environmental condition of a sphagnum bog (acidic pH, low temperature, lack of O$_2$) leads to preservation of soft tissues by tanning. Preservation by lithification is thus not a common fate of a dead body and will occur only under special circumstances. As a result, not all places in the world have the same likelihood of bearing fossils somewhere under the surface. For instance, the acidic soil conditions of densely forested areas do not permit fossilization at all. Karstic caves, on the other hand, are characterized by low temperature fluctuations and slightly alkaline conditions, which constitute a nearly ideal environment for fossilization (Weiner et al. 1993). Normally however, complete decomposition is the normal fate of a dead body, and the speed of the processes involved depends on the local burial environment. The tissues will normally suffer from stepwise destruction, and some destruction usually also precedes preservation.
Abiotic and biotic factors may both be responsible for the alterations of dead bodies in the course of necrology, biostratinomy, and diagenesis. These processes are also referred to as “first-order changes” because they are independent from archeological activities and are opposed to “second-order changes,” which are under control of the archeologist, such as choice of site (where to excavate), excavation technique, etc. (Reitz and Wing 1999).

Preburial modification of body parts is brought about by scavenging, gnawing, digestion, butchering, weathering, trampling, transportation, and heat exposure. Postburial modifications are the result of the burial environment, which is characterized by the availability of water and oxygen, temperature, pH, abundance of microorganisms, faunal and floral elements, and ion concentrations. Many taphonomic changes may resemble pathologies or even intended manipulations and give rise to killing or cannibalistic scenarios—another facet of taphonomic research, which is responsible for distinguishing a biological signal from a taphonomic alteration.

The amount of paleobiological information that can be deciphered from a fossil is a function of all three steps of its taphonomic history. For instance, the body of individuals that died of predation have a smaller chance of preservation because the mineralized body parts will undergo at least some partial destruction by chewing and stomach acid etching. In ideal, rare cases, individuals are caught in natural traps like the famous La Brea tar pits in California. Such sites can contain fairly large amounts of accumulated fossil bones (Shipman 1981a). Catastrophic death due to flash floods, volcanic eruption, etc. has to be distinguished from attritional death by natural causes, since the age structure of the resulting bone assemblage will differ drastically. While catastrophic death leaves a sort of snapshot of a formerly existing animal community, attritional death will lead to an overrepresentation of the more vulnerable very old, very young, and diseased individuals.

The majority of alterations to vertebrate skeletons later recovered in fossilized form are due to biostratinomical processes. Thus, the recovery of a nearly complete fossilized skeleton or even of several parts of the same skeleton (e.g., the case of Australopithecus afarensis A.L. 288-1 “Lucy,” or the “Nariokotome Boy,” H. erectus KNM-WT 15 000) is exceptional. Usually, single skeletal elements or their parts are recovered out of their former anatomical context, with teeth constituting the majority of fossil finds. This is the result of the natural disarticulation sequence of a vertebrate body, which is altered and enhanced by predators or scavengers, and which depends on the structure and composition of an individual bone. The over- or underrepresentation of specific skeletal
elements at the australopithecine site of the Makapansgat Limeworks has already been stated by Dart (1957), and was confirmed at the Sterkfontein, Swartkrans, and Kromdraai sites, giving rise to both experimental and field work (Brain 1967). Still, a major concern of taphonomic studies is the differentiation between natural and cultural origins of bone accumulations, and experimentation, the results of which are necessarily interpreted by uniformitarian assumptions, is usually straightforward despite its inherent limitations (for review, cf. Nicholson 2001, Denys 2002).

The mobility of joints and the presence of more resistant tissues like tendons control the natural disarticulation sequence. First, the skull and limb bones are disconnected, followed by the ribs. Next, the limb bones and the lower jaw become disarticulated, only when the final stage is reached, when weathering will mostly have already set in, does the vertebral column become scattered (Toots 1965). Once skeletonized and disconnected, the resistance of individual bones toward further destruction is a function of bone density (Lyman 1984), at this stage, the process of destruction appears to be rather constant and less a function of the exact taphonomic context (Stojanowski et al. 2002). Best preserved are skulls, followed by the shafts of limb bones and their denser epiphyseal parts, while the sternum, clavicle, and scapula are usually the least well preserved. Teeth have a very good chance for preservation because of their high density, small surface/volume ratio, and overall small size, which favors rapid embedding.

7.4.1 Preburial modification processes of body parts

7.4.1.1 Weathering and trampling

When talking about weathering, most people intuitively think of bone exposed to climatic conditions while it is still on the surface and not yet buried. Behrensmeyer in her pioneering fieldwork defined six stages of bone weathering: from stage 0 (no cracking or flaking) to 6 (bones mechanically fall apart into pieces), but made it clear that weathering may destroy a bone in situ “either on surface or within the soil” (Behrensmeyer 1978). While it is a common occurrence that bones buried within the soil may still “weather,” although at a much slower rate, the main interest of paleontologists, anthropologists, and forensic scientists is to define the time a skeletal element has spent on the surface, or how much time has elapsed until a bone assemblage was formed (Potts 1986). In their critical evaluation of Behrensmeyer’s weathering stages and the conclusions drawn from them, Lyman and Fox (1997) confirm the main factors governing bone weathering (size and density, species-specific texture, stability of the
environment—three factors only, but enough to render the process quite com-
plex), but clearly point out that one is still “a long way from safely inferring time
of bone assemblage formation, let alone hominid behavior, on the basis of bone
weathering data.”

In the course of the weathering sequence a bone undergoes while still on
the surface, longitudinal fractures appear first, followed by fractures running
transversely to the shaft of a long bone. Fragments which become abraded, may
resemble bone artifacts like needles and awls. Miller (1975) pinpoints that there is
an “ever-present danger of misinterpreting bone that had been altered by natural
causes as artifacts.” Needle-like bone splinters even with holes, strongly resem-
bling needles at first glance, may be the product of stomach acid etching after
bone ingestion by scavengers (Sutcliffe 1970).

Experimental work revealed that trampling of a bone can produce scratches
by sediment grains that strongly resemble cut marks. Real cut marks, in contrast,
may be completely erased by trampling. This is another example of pseudoarti-
facts which have been mimicked by natural phenomena, and which can lead to
serious misinterpretations of a fossil. It has therefore been emphasized that a
correct identification of cut marks is greatly supported by their location on a bone
(site of ligament or muscle attachments), and by their microscopic features
(Behrensmeyer et al. 1986).

7.4.1.2 Transportation

Although whole bodies can be transported away from the original place of
death by such agents as floods, the likelihood of transport is much higher for
disarticulated body parts. These are taken away by predators and scavengers
or are relocated by wind currents or gravity. However, “water is perhaps the
most ubiquitous taphonomic agent transporting, modifying, and accumulating
remains” (Haglund and Sorg 2002). The authors emphasize that many fossil
hominid finds, such as the Nariokotome Boy or the australopithecine “First
Family,” have been recovered from sand or gravel sediments deposited by moving
water, which are highly suitable for rapid embedding and burial. Since water
environments differ in current, temperature, depth, salinity, and other features,
disarticulation sequences and decomposition processes of a dead body are diffi-
cult to predict. Experimental taphonomic work with human bones in an artificial
flume, which constitutes an ideal and not a natural water transportation simul-
ation, have revealed different transport groups of bones according to their size and
shape (Boaz and Behrensmeyer 1976). This does not only lead to a removal of
skeletal parts from their original place but also to a sorting of the bones in terms
of their morphological properties. Certainly, water transport causes additional damage to bones, especially by abrasion in sediment-rich water.

### 7.4.1.3 Scavenging and gnawing

It is the scavenger’s business to clear dead bodies from a site. Spontaneously, one would think of middle-sized mammals, like hyenas, but also small rodents, toads, and some land snails are also efficient scavengers. Many more species gnaw bones, mostly to meet their calcium and phosphorus demands. These include nonhuman primates, canines, weasels, raccoons, hyenas, cats, artiodactyls, squirrels, beavers, mice, rats, porcupines, rabbits, hares, varanids, and some desert tortoises (cf. Reitz and Wing 1999). Osteophagia is especially common in artiodactyls (cattle, red deer, reindeer, muntjac, camels, and giraffes) as a symptom of phosphorus deficiency in regions with low phosphorus content of parent rocks. Since the bones are chewed with the molars, such gnawed bones reveal a pattern resembling forks and prongs, which may again be mistaken for human artifacts (Sutcliffe 1973). Rodents, which have to wear their ever-growing incisors, leave very characteristic gnaw marks, preferentially on the edges of the bone, in the form of parallel grooves. Bite marks left by carnivores do not occur as parallel grooves but as irregular grooves and pits (Figure 7.2). Four types of tooth marks, namely, punctures, pits, scoring, and furrows, have been identified by Binford (1981). The trabecular parts of the bones may be completely consumed, and the thicker compact shaft will exhibit splinters and sharp, pointed ends (Haynes 1980; Eickhoff and Herrmann 1985). According to Shipman (1981a), carnivore tooth marks have a V- to U-shaped cross section. Bones that have been digested are eroded and pitted by stomach acids. They are usually of very small size and will mostly be recovered only by sieving feces or regurgitants.

Fossil bone assemblages raise the question whether the bones have been accumulated by scavengers or by hunters (natural versus cultural accumulations), especially in the case of early hominids, which are assumed to have practiced a mixed hunting–scavenging subsistence strategy (Shipman 1986). Extensive fieldwork revealed a fairly general consumption sequence of medium to large sized carcasses (Blumenschine 1986): consumers proceed in two cycles from the back to the front of the carcass, consuming, first, the easily accessible, high-yield nutrients of the flesh and viscera, and, second, the more difficult-to-access bone marrow and brain (Figure 7.3). Blumenschine (1986), therefore, postulated a relationship between body part representation and an inverse consumption sequence. Bone assemblages due to hunting consist of more or less complete sets of body parts including those with large, easily accessible, meaty portions,
whereas bone accumulations as a result of scavenging should consist of the less valuable parts of a carcass. A reevaluation of the hominid fossils recovered from Sterkfontein Member 4 (Pickering et al. 2004) in fact revealed that the paucity of postcranial remains, and the carnivore tooth marks on the fossils, strongly supports the "carnivore-collecting hypothesis" as the underlying mechanism for the accumulation of fossils at this site (cf. Brain 1981). Forensic studies

Bite marks on the epiphyseal end of a tibia from a sheep/goat. Punctures are produced by canine teeth. Bones from juvenile animals like this one are rather soft and easy to chew. Note the additional cut mark at the right lower end of this fragment. The bone thus shows features of both butchering and gnawing. Photo: S. Bischler

Figure 7.3
General consumption sequence of carcasses according to Blumenschine (1986). Deviations from this general pattern are due to carcass size, age of the dead individual, and consumer type.

First cycle:
- Tissues outside bone (flesh, viscera)

Hindquarter: posterior of rib cage

Forequarter: postcranial incl. rib cage

Head

Second cycle:
- Tissues inside bone (marrow, brain)
also confirmed that canid disarticulation of human bodies follows this rather consistent sequence but may cover highly variable time spans. Total disarticulation was achieved between 5 and 52 months and characteristically, the cranium could always be recovered in contrast to other skeletal elements (Haglund 1997).

### 7.4.1.4 Butchering

Butchering marks are cut marks produced by the tools utilized in the process of dismembering or skinning a carcass (Figure 7.4a and b). While their cross section may be very similar to carnivore bite marks, they frequently exhibit fine, parallel striations (Shipman 1981a, b; Eickhoff and Herrmann 1985) and have specific locations on the skeleton. According to Noe-Nygaard (1989), butchering marks reflect the tool type; hence, cut marks can be distinguished from scrape marks, hack marks, saw marks, and blows. Blows, especially, will fracture the bone and

![Figure 7.4](a) Cutmark on a pig calcaneus. Photo: S. Bischler, (b) Damage to a pig tibia due to butchering that permitted access to the bone marrow. Photo: S. Bischler
serve getting access to the bone marrow. According to experiments carried out by Walker and Long (1977), cross sections through a cut mark permit the identification of the tool, and the shape and depth of cut marks varies with the applied force. Other experiments by Bromage and Boyde (1984) open up the possibility of telling the directionality of cut marks on bone, which would give clues to the handedness of their producers. However, the microstructural properties of the marks are highly dependent on the bone properties (type of bone, bone density, etc.).

### 7.4.1.5 Heat exposure

Excluding cremation as a special burial custom, and all cannibalistic scenarios, food processing is the most probable event when a bone is exposed to elevated temperatures for a prolonged time, and this will hold for animal bones in the majority of cases after hominids became capable of controlling fire. As long as a bone has been in direct contact with the heat source, burning and incineration will leave characteristic traces. Even after very short exposure, when charring is still absent, the denatured collagen will produce both longitudinal cracks (similar to those produced by weathering) and also transverse cracks in the bone, which are the result of recoiling of broken collagen fibers that had been previously under tension (Shipman 1981b). As long as the bone is protected by surrounding flesh during baking, roasting, or boiling, heat exposure remains undetectable macro- and microstructurally. Heating experiments in which whole bovine bones were boiled for several hours revealed that protein loss is accompanied by increased crystallinity and porosity, effects that might cause accelerated diagenetic deterioration (Roberts et al. 2002). If this hypothesis holds true, another bias in terms of the composition of bone assemblages will have to be expected. However, diagenetic processes (see in the following section) may have precisely the same effects.

### 7.4.2 Postburial modification processes of body parts

#### 7.4.2.1 Diagenesis

Diagenetic processes are controlled by the various features of the burial environment, that is the availability of oxygen and water, temperature and its fluctuations, soil pH, the presence of soil flora, soil fauna and especially soil microorganisms, and the availability of free ions (Figure 7.5). Biodegradation can thus be differentiated from chemical degradation, but both pathways are usually intertwined.
Moisture, temperature, and pH are responsible for the abundance of soil microorganisms, which get easy access to a bone by invasion through the natural hollow spaces. Microorganisms consume organic matter to meet their energy demands; therefore, the biological breakdown of a bone’s organic constituents is also far from random (Balzer et al. 1997). Primary metabolic products of this organic matter metabolism are CO₂ and H₂O. In addition, many microorganisms are capable of secreting acid metabolites, which will subsequently dissolve the biological apatite, leaving characteristic destructive foci (Figure 7.6). Many bacteria, like those of the genus Streptomyces, are capable of selectively cleaving collagen by their collagenases. Consequently, collagen is lost from the bone, leaving a higher porosity of the specimen. Together with the focal destruction, the surface area of the specimen is enlarged (Grupe 2001). Even in the absence of microorganisms, soil pH may lead to a slow loss of collagen from a bone by chemical hydrolysis (Figure 7.7). Mineral infilling of the diagenetic porosities is considered a key mechanism leading to bone fossilization (Collins et al. 2002).

In general, it is plausible that microbial invasion of a buried bone plays a key role in bone decomposition, since prolonged microbial attack will prevent fossilization and accelerate breakdown. Since microbial activity is temperature and moisture dependent, warm and wet climates will not be suitable for bone preservation. Exposure to excess humidity on the other hand will reduce the necessary...

Figure 7.7
Subfossil human bone (Göbekli Tepe, Anatolia, 9500–8500 cal BC). While the microstructure is well preserved with the exception of several microfissures, this specimen did not show any birefringence under polarized light. No collagen was retrievable from this specimen. Photo: S. Dummler
oxygen supply, and microbial activity is suppressed. Microbiological diagenesis is also reduced in cold climates (Grupe 2001).

The enlarged surface area is an important factor in decomposition rates (Gill-King 1997), since the exchange of matter (minerals and ions) between bone and the surrounding soil is facilitated. Exposed bone mineral may be subject to heteroionic substitution, supporting fossilization. Several elements are prone to be taken up by the bone, especially F, U, and rare earth elements (REE), whereby the latter serve as indicators for considerable diagenesis (Metzger et al. 2004). More frequent however, is the chemical dissolution of the apatite by hydrolysis, depending on the soil pH. This will result in free ions, mainly calcium and phosphate ions, which will either be leached from the bone by soil moisture and precipitation or be recrystallized as soon as a critical ion density is reached (White and Hannus 1983). This recrystallization and/or the preferential loss of smaller crystallites in the course of mineral dissolution leads to an increase of the bone’s crystallinity, a most fundamental aspect of bone diagenesis (Person et al. 1995; Nielsen-Marsh and Hedges 2000). Newly formed crystals are generally more soluble than the original bone mineral, and disintegration proceeds. This holds for instance for the transformation of the original bone mineral, a calcium-deficient hydroxyapatite [Ca$_5$(PO$_4$)$_3$(OH)] into brushite [CaHPO$_4$·2H$_2$O] as described by Herrmann and Newesely (1982). However, recrystallization may also lead to more stable mineral configurations and is therefore a means of fossilization.

7.5 Conclusions

As time progresses, the conditions of a burial environment may change considerably. Therefore, any excavated bone specimen exhibits a certain status quo of its diagenetic history, which is hard to unravel in detail. Considering the gross diagenetic processes, it is obvious that certain environments are more conducive to preservation (anoxia, dryness, cold temperatures), while others enhance decomposition. It is a common occurrence that rather young archeological bones may be much less well preserved than older ones. First, the simplistic explanation holds that a well preserved or even fossil specimen must have been buried in a preserving environment. Second, diagenesis should also be considered a self-limiting process in many cases, especially when the burial environments are favorable for mineral infillings, recrystallization, and ionic replacement (Figure 7.5). Therefore, the majority of recovered specimens will have undergone diagenesis to a certain degree. Since progress in methodological innovations today permits the retrieval of even trace amounts of organic molecules like collagen,
noncollagenous proteins, lipids, and DNA, all of which potentially yield very useful, diverse, and otherwise nonachievable information of the once living organism, the understanding of diagenetic processes today mostly focuses on the means and speed of the deterioration of biomolecules. Many studies, therefore, attempt to define easily obtainable predictors for molecular preservation (Götherström et al. 2002).

Acknowledgments

My special thanks are to the editors of this handbook for inviting me to contribute to this volume. Susanne Bischler, MA and Sara Dummler, Dipl Biol kindly provided some of the figures, and George McGlynn, MA edited this manuscript.

Abstract

This chapter looks at the potential explanatory power of archeology as a paleoanthropological discipline. Through the study of artifacts, archeology provides insight into tool use as a major part of human behavior. Five facets of archeological knowledge can be drawn from the material remains of object-bound activities: typological, technological, functional, contextual, and cognitive information, from which other behavioral aspects, like subsistence, settlement, social organization, and their cognitive background, can be derived. Yet, archeological analyses face significant constraints. A brief outline of Paleolithic artifact history shows how this part of the behavior of *Homo* developed, which is accessible by archeological remains. Following the question “What could they do?” the cognitive basis of that behavior is tracked down in its phylogenetic-biological, ontogenetic-individual, and cultural-historical dimensions. The study of the evolution of the human mind is still at its beginning in archeology. Six different approaches are given as examples.

8.1 Introduction

Archeology is the anthropological field that studies the material cultures of former human populations. The most ancient of these populations are the subject of Paleolithic archeology, which deals with the material remains of early hunter-gatherers, from the first stone artifacts of 2.5 million years ago to artifacts documenting the initial steps toward sedentary life and agriculture at the end of the last Ice Age. Paleolithic archeology is often perceived as studying typical and rather invariant Oldowan, Acheulean, or Middle Paleolithic stone artifact assemblages that sometimes accompany human fossils. Moreover, because archeological analyses of these associated finds has remained fairly dissociated from evolutionary discussions in physical anthropology, the assumption has formed that human design, production, and use of tools stagnated during at least the first 2 million years (Myr) of their existence. In fact, however, Paleolithic artifacts are considerably more informative than this: they provide clues to early human behavior and
attest to hominins’ increasing capabilities and efforts to get beyond the physical limits of their bodies by using tools. Although tool use and manufacture do occur occasionally in the animal kingdom—ranging from the use of unmodified objects in one specific context that some species of invertebrates, insects, birds, and mammals have developed to the tools adaptive to different problem settings that primates, especially great apes, and some bird species, namely crows, tend to use—as will be described later, tools emerge as an eminently human production indeed. For modern humans, who have created an artificial world, tools are their second nature. How we got from our occasionally tool-using primate ancestors to a species that is helpless without tools can be traced only by following the development of artifact assemblages. Therefore, this chapter will focus on the potentials and limitations of interpreting artifacts and tools found in archeological contexts to illuminate this special human character.

8.1.1 Definitions

As a prelude to the study of tools and tool use, three terms must be defined: “archeology,” “artifact,” and “tool.” Archeology, in a broad sense, can be defined as the search for human activity zones, the recovery and documentation of these zones, and the analyses of remains (artifacts) and their interpretation. The main purpose of the discipline is to study artifacts made and used by prehistoric populations in order to reconstruct human material culture and activity patterns and thereby elucidate the development of humans as cultural beings (Figure 8.1). To this end, the raw data from excavations undergo analysis and sometimes additional experimental studies on the manufacture and use of artifacts and on the processes through which sites have developed over time. Insights into the origin and formation of artifact assemblages may also be gained by examining the object behavior of living human groups under ethnoarcheology (Binford 1978) or by comparatively analyzing the material remains of recent primate activity (Mercader et al. 2002). In sum, artifacts constitute the main material basis of archeological studies. Animal and plant remains from human activity areas are also analyzed, and dealt with as artifacts if they were used by human beings, to provide information on environmental parameters that influenced human behavior. Finally, human skeletons can be subject to archeological research insofar as they either were manipulated—and therefore can be handled as a sort of artifacts—or show physical features induced by certain activities.

Artifacts and tools are overlapping but not synonymous categories. While tools and their functional use are the main focus of studies of animal behavior, archeology concentrates on the artificial aspect of manipulating objects in human
context. This point of view is summed up by Hahn (1993), who differentiates among natural objects, items in human context, and things which show signs of human use. Following his definition, the category “artifact” includes all material objects manipulated by humans, from a stone moved by an individual to clearly human-made pits, hearths, and stone structures. More narrowly, Hahn defines artifacts as items of stone, wood, or other materials that show at least some indicative use-wear, whether the objects are separate from or fixed to the environment. The term “tool” bears a technological meaning in archeology as a subcategory of artifacts: they are freely movable objects and were commonly modified in several operational steps, conditions which are not necessary to be accepted as an artifact. Thus an artifact blank can become a tool intentionally by modification—as in the case of stone flakes reworked into scrapers, denticulates, and burins, for example—or unintentionally by use for some functional purpose, as evidenced by use-wear and retouches on an unmodified blade.

In contrast to the archeological viewpoint, primatologist Beck (1980) defines tools not technologically by the object itself but by the functional use to which an object may be put. Tool use, he writes, is “the external employment of an unattached environmental object to alter more efficiently the form, position, or condition of another object, another organism or the user itself when the user holds or carries the tool during or just prior to use and is responsible for the proper and effective orientation of the tool” (Beck 1980 p 10). Thus, Beck
excludes clearly artificial structures, like nests, pits, or other fixed artifacts, which are quite common in animal species and are often highly complex, such as the elaborate nests of bower birds, classifying these as the material outcome of a different, nontool behavior. Ergonomist Christopher Baber (2003 p. 8) identifies a tool as “a physical object that is manipulated by users in such a manner as to both affect change in some aspect of the environment and also to represent an extension of the users themselves. The manipulation is directed toward a specific goal or purpose, and the associated activity requires a degree of control and coordination.” Accordingly, in this functional sense, a simple form to cut out cookies is a tool but even the most sophisticated cookies themselves are not: those are mere artifacts of tool use.

The ethological definition of tool use differs from the archeological one in two ways: tool use is not restricted to human behavior and objects fall into the category of tools by their use, irrespective of the technical aspects of use-wear and modification that characterize archeologically defined tools. Thus Beck, dealing mainly with directly observed behavior, is but marginally concerned with the material evidence of use on the artifacts; and for zoologists generally, who focus on behavior and are only in passing documenting the material inventory of populations or species, the technological details are of minor interest. As a result, a major problem in Lower Paleolithic archeology, that of identifying artifacts and used objects made from durable material, is excluded from the domain of ethologists studying modern animal tool behavior. For archeologists, however, who consider the use and manufacture of objects as a characteristic human means to increase the physically limited abilities of the body in solving problems, the functional separation of tool use sensu stricto from the formation of attached or unattached artificial structures is irrelevant. Both can be subsumed under the category of artifacts to get a more complete picture of the material culture, the subject central to archeology. What sort of information artifacts do yield through archeological analyses will be discussed next.

8.1.2 Facets of archeological knowledge

Through the use of diverse methodological approaches, five major facets of knowledge can be drawn from archeological artifacts. These facets can also be combined to generate pictures of different aspects of prehistoric life like settlement and subsistence behavior, social and religious organization, technical progress, and the spread of innovations.
Typological facet: Artifacts tell us what forms and styles of objects typify a group. Artifact types are defined by features of form or style as perceived by modern analysts, and changes in types through time, as seen through stratigraphic analysis, seriation, or both, form the basis of relative chronology. The definition of cultural groups and their geographical distribution is founded on the relative spatial separation of artifact types.

Technological facet: Artifacts tell us the materials and operational steps used to make tools. By analyzing the different operational steps in tool production, their order, and the variation in that production sequence, we can gain insight into the basic crafts of past societies. Further, a survey of the implements necessary to make certain artifacts gives evidence on the complexity of human object-behavior. In addition to technological studies, the management of raw material is examined to see, for example, if raw material was taken by chance, if certain raw materials were preferred, or if special raw materials were used for particular artifacts. The effort taken to procure the raw material for artifacts and the degree of extensive or intensive exploitation are further relevant to developing hypotheses on how former people differentiated and evaluated technological qualities. A combination of typological and technological aspects of knowledge may refine an artifact typology and can give information about group- or period-specific employment of crafts.

Functional facet: Artifacts reveal not only the technological aspects of how they were manufactured and got their form but also how they were used. Through experimentation, use-wear analyses can indicate the activities and ways in which artifacts were employed. Additionally, functional examination can give evidence about behaviors whose resulting artifacts may be only rarely preserved such as the manipulation of organic raw material (Soffer 2004). Further, experiments with reconstructions, as in the case of the wooden spears from Schöningen/Lower Saxony (Rieder 2003), can test hypotheses on qualities of tools. The examination of specific functions related to special artifact types reveals formal categories already set up at the time of the use of the tools. In all, a combination of functional and technological analyses can disclose the life history of artifacts with sequences of repeated modification and use as well as hypothesize which functional necessities of a tool influenced its manufacture.

Contextual facet: Artifacts tell us, from their location in a site, where they were made and used, and suggest how sites and life within them were organized. Based on detailed three-dimensional documentation of where artifacts, tools, and waste were found, combined with refittings of production sequences, loci of activity can be classified as dump zones, ateliers,
food processing areas, etc. The spatial and chronological relations between the identified activity zones and between contemporaneous sites allow conclusions on the organization of prehistoric life.

- **Cognitive facet**: Artifacts tell us what kinds of decisions either deliberately or unconsciously underlie their conceptualization, manufacture, and use. Thus comparative analysis of data from the four previous facets can reveal preferences in how tools were designed, produced, and used and where on a site they were made or used, pointing up less favored or rejected alternatives. Information on a population’s artifact array, combined with environmental constraints, give hints about the range of behavioral choice and aspects of decision-making in typology, technology, use of artifacts, and site organization. In this way, the spectrum of the decisions taken by a group exposes its knowledge about and comprehension of the world, its cognitive capabilities and the processes of cultural diffusion underlying artifact types, production and use; in rare cases, as at the French Magdalenian sites of Etiolles (Pigeot 1990) and Pincevent (Ploux 1989), even individual behavior and apprenticeship can be perceived.

In these five aspects of archeological knowledge derived from artifacts, it becomes obvious that the archeological discipline is a combination of science and humanities not only in its questions and collected data but also in its approach to knowledge. While the technical, functional, and contextual aspects are scientifically oriented, yield somewhat reproducible facts, and are open to experimental falsification (not in the hard scientific sense but in the sense that, for e.g., wear patterns on a tool can be repeatedly examined, and hypotheses on their origin tested), the typological and, even more so, the cognitive facet adopt a humanities-oriented hermeneutic approach. This attitude of knowledge looks not so much for identification of facts and rules but for understanding of background patterns. Of course, this differentiation between scientific–empirical and humanistic–hermeneutic approaches in archeology can reveal only tendencies: almost all archeological works are a mixture of scientific observations and resulting statements with hermeneutic interpretation. The gradual preference of the one or the other depends very much on theoretical standpoints of the analyst.

### 8.1.3 Limits to archeological analyses

Despite the discipline’s remarkable insights into otherwise undisclosed aspects of everyday life, archeology is able to give only an incomplete and fragmented picture of prehistoric activities and behavior. Several preconditions have to be
met so that archeological analysis may gain access to at least some sectors of hominin living.

First, to become archeologically evident today, behavior in the past must have caused a detectable change in the natural environment, producing artifacts or leaving other material traces behind. This prerequisite severely diminishes archeological studies to a small but nonetheless important portion of the full range of human behavior.

Second, the artifacts must have been embedded in sediment, and the sedimentation should have proceeded quickly, but not aggressively, so that the activity context of the artifacts is sealed carefully. This is a key point, for large parts of the information record can be lost due to taphonomic processes in slow or incomplete sedimentation and to secondary alterations of the find-bearing strata like erosion and bio- or cryoturbation.

Third, the artifacts must have been preserved over time. A wide range of artifacts made from organic material, for example, is likely to have weathered to unrecognizable shapes or to have decomposed altogether. Physical and chemical destruction of different substances depends very much on climatic and soil conditions, with cave sediments in temperate zones being most favorable for many raw materials and the acidic red soils of tropical regions among the worst areas for conservation.

Fourth, the artifacts must be discovered. Further, they have to be unearthed with documentation of their context to reveal the maximum information they still bear. The quantity of archeological evidence in an area or a period is a direct function of the density of research activities and the exposure of relevant geological strata by natural means or through quarrying or construction work.

Finally, the traces of behavior kept in the artifacts must be accessible to interpretation. This can depend on actual research paradigms, the possibilities and availability of analytic methods, as well as individual or social limitations affecting the analyst.

In Paleolithic archeology, another problem arises from the difficulties in ascribing artifacts to one of several contemporaneous human species established by fossil remains in the same region. For example, although the first stone artifacts are widely accepted as the products of early Homo habilis or Homo rudolfensis, there are also robust australopithecine candidates for authorship because of their hand morphology, which, in principle, would have enabled them to knap stones (Susman 1991), and it is unclear who made the cut-marks on bones associated with Australopithecus garhi fossils at Bouri/Ethiopia (de Heinzelin et al. 1999). These uncertain attributions hamper the linkage of behavioral data and information derived from physical–biological context and thus obstruct the deciphering of the evolutionary implications of cultural remains.
8.1.4 Archeology as a paleoanthropological subject

While clues to the behavior of deceased species and populations are limited, functional morphology may give insights into general aspects of living by analyzing dentitions adapted to certain diets, or limbs allowing special ways of locomotion, or other features of the genetically-based layout of the body.

From the physique, behavioral possibilities can be ascertained. A generalized hand, with opposable thumb and the capability of power and precision grip, is able to do what a hoof or fin cannot. Fossil skeletons of Homo and other hominins show bipedal primates developing lower limbs specialized for long walks and free hands perfect for object manipulation. But the question of whether robust australopithecines in fact used their in principle capable hands (see earlier) to produce Oldowan artifacts must remain open, as must the actual use made of the enlarging brains that accompanied the evolution of the genus Homo. Only a few features observed on skeletons can be attributed to concrete activities; in most cases, rather unspecific characteristics, like robustness of the bones, are hard to interpret (Bridges 1995), and these limitations are compounded by the sparseness of the skeletal database and lack of systematic examination of the modern reference. Trauma patterns of Neanderthals apparently paralleling those of modern rodeo riders (Berger and Trinkaus 1995) are a chance result that remains singular.

More productive are correlations between basic physical capabilities, including the cumulative markers of effort, stress, and nutrition that can be deduced from skeletons, and artifacts, which yield detailed information about actual behavioral episodes. This explanatory power of artifacts may be demonstrated with regard to the issue of subsistence, as the prominent behavioral aspect that can be derived from Paleolithic archeological remains. For years, the question has been discussed of whether some of the human ancestral groups were hunting or actually scavenging (Blumenschine et al. 1994). While traces from carcass-processing give evidence of the range of the prey according to species and age distribution, as well as show the use of the different body parts, finds like the spears from Schöningen (Thieme 1997) indicate sophisticated hunting activities among H. heidelbergensis. Similarly, clues to the composition of the diet can be gathered not only from the zoological and rare botanical remains from archeological sites but also from markers detected on artifacts. Thus digging for termites, well known for chimpanzees, may also be likely for Australopithecus robustus based on the use-wear analysis on bone tools (Blackwell and d’Errico 2001); and starch grain analyses of stone tools demonstrate that the selection and processing of barley and wheat was underway in Southwest Asia at least 12,000 years before these grains were domesticated (Piperno et al. 2004). A third
example is the control of fire which reaches back at least 790,000 years at Gesher Benot Ya’akov/Israel, from which certain artifacts show burn marks that can be explained only as exposure to controlled, not natural, fire (Goren-Inbar et al. 2004).

Another important issue in Paleolithic archeology that is accessible through artifact analysis is settlement behavior. Artifacts from a range of settlement sites, from short-term camps with nonspecific structures to long-term dwellings at favorable locations, like Upper Paleolithic Dolní Věstonice, Gönnnersdorf, or Pincevent, yield information on the organization of everyday life and on people’s mobility, group size, differentiation, and separation of activities.

It is clear from these artifact remains that places reserved for special activities developed quite early in human evolution, underscoring that resource management is a key factor in human behavior. There were repeated purposeful visits of early Homo to the 1.6-Myr-old MNK Chert Factory Site in Olduvai Gorge Bed II, a tool manufacturing site with more than 30,000 documented artifacts made from raw material brought in from about a kilometer away and distributed over an area at least a kilometer from the site (Stiles 1991). At the Middle Pleistocene “horse butchery site” Q2 GTP 17 from Boxgrove, H. heidelbergensis brought six to seven flint nodules from the cliff some hundreds of meters away and flaked them into handaxes for the immediate purpose of cutting up the carcass of a horse (Roberts and Parfitt 1999). In analyzing the raw material and artifact transport to and from such sites, the development of larger and more complex settlement systems and territorial organization in human evolution can be brought to light (Féblot-Augustins 1999).

As a paleoanthropological subject, archeology can complete the results of other anthropological disciplines in several ways. In analyzing artifacts, archeology gathers information from short-term behavioral episodes which originate from singular or repeated events and can be fused to a more general picture of the behavioral aspects of chronologically, spatially, or biologically distinctive groups. Furthermore, comparing these results diachronically opens a cultural-historical dimension, thus making the evolutionary perspective on human behavior, and its underlying cognitive development, accessible in its full range. This will be described in more detail in a later section.

### 8.2 What they did: A brief outline of Paleolithic artifact history

As an overview on historical knowledge derived from artifacts, and basis for a succeeding discussion of human cognitive evolution, this section covers the major
behavioral developments which can be extracted from archeological remains; short sketches only, they are organized in roughly chronological order.

The earliest artifacts to which hominin authorship is assigned are stone tools reported from Gona, Ethiopia (Semaw et al. 1997) dated to 2.5 Myr BP. Contrary to earlier assumptions that the initial phases of the Early Stone Age (Lower Paleolithic; the Oldowan and the succeeding Developed Oldowan A technocomplexes) could be characterized by a core tool technology with distinctive tool types as intentional end products, experiments have shown that the Oldowan core tools vary with the raw material used (Toth 1985). However, beside simple technologies with coarse raw material from which few flakes were detached, there are examples of higher-quality raw material processed in longer operational sequences (Kimura 1999) with up to 30 flakes removed, both unidirectionally and multidirectionally, from both natural and prepared platforms (Roche et al. 1999). Flakes, few of which show intentional retouch, served mainly as cutting devices, while cores which were typologically classified in categories, such as choppers and chopping tools, were used as heavy-duty tools. In the first million years of human stone artifact production, raw material transport did not exceed some 5–10 km. No manufacture of bone tools has been proven so far, yet in rare cases the use of bone has been documented (Brain and Shipman 1993). Early sites with Lower Paleolithic artifacts are located in East and South Africa, but by around 1.8–1.7 Myr, the first migrants to West Asia (Dmanisi) (Gabunia et al. 2000) and presumably to East Asia were also been equipped with similar technology. Throughout the Oldowan period, observed site organization is widely unspecific with focus on processing carcasses and/or stone tool production (Stiles 1991). Simple settlement structures have been postulated at Olduvai Gorge, Tanzania, and Melka Kunture, Ethiopia, for example, but these claims are mostly rejected today due to possible natural explanations.

With the Acheulian, a new technological concept of bifacial tools with specific intentional forms, like hand axes and cleavers, was introduced around 1.5 Myr (e.g., Konso-Gardula, Ethiopia) (Asfaw et al. 1992). This technology eventually spread from the Early Acheulian sites in Africa to later sites in Asia and Europe. Although the Acheulian bifacial concept dominates the perception of that period, these artifacts are in fact copresent with flake tools, though these are often, possibly falsely, classified as spatially and/or chronologically distinct industries like the Clactonian and Tayacian in Europe or the Developed Oldowan B in Africa (White 2000). Movius (1949) has observed that East and Southeast Asia seem to have been completely excluded from the spread of the bifacial technology concept, but recent finds from the Bose valley of Southern China (Hou et al. 2000) dating to around 0.7 Myr cast doubt on this hypothesis. Probable evidence of the control of fire as a typical human artifact is increasing
with the 0.79–Myr-old finds from Gesher Benot Ya’akov, Israel (Goren-Inbar et al. 2004), although some instances of fire use, such as at Zhoukoudian /China from the end of the Lower Paleolithic period, have been questioned (Weiner et al. 1998).

From the very end of the Lower Pleistocene on, human occupation has also been proven for Europe, e.g., at Atapuerca TD6, Spain (Carbonell et al. 1995), with human fossils strengthening the weak artifact evidence. Although the material remains of Homo behavior become more numerous in the subcontinent from 0.5 Myr on, it is not likely that the whole of Europe was populated continuously. The observed artifact spectrum widens in the Middle Pleistocene with wooden spears and other tools, e.g., from Clacton (Oakley et al. 1977), Schöningen (Thieme 1997), possibly Bilzingsleben (Mania and Mania 1998), and Gesher Benot Ya’akov (Belitzky et al. 1991). A few flaked bone tools have been documented in that period but no bone or ivory projectile points (Villa and d’Errico 2001). Evidence of nonfunctional artifacts, such as at Berekhat Ram (d’Errico and Nowell 2000), Hunsgi (Paddayya 1977), and Bilzingsleben (Mania and Mania 1988), is very scarce. Postulated settlement structures at Bilzingsleben (Mania 1983) and the Grotte du Lazaret (de Lumley 1969) are questioned.

In the final phase of the Lower Paleolithic, and continuing into the African Middle Stone Age and the European Middle Paleolithic, flakes were increasingly retouched to improve or create the working edges of tools like scrapers, denticulates, notched pieces, and special forms of knives. The rising focus on flake tools can also be traced in Levallois technology, a new concept in stone knapping that first appeared between 0.3 and 0.2 Myr. The idea of characteristically prepared Levallois cores, which allow predetermined flake forms, did not replace the older concepts but was used in addition to them. In the European Middle Paleolithic, distances of raw material or tool transport increase up to 100 km or, in some cases, more (Féblot-Augustins 1999). Artifact assemblages of the Upper Pleistocene after the last interglacial also reveal increasing complexity and diversification. Microwear patterns and use of hafting materials, like a piece of birch tar at Königsaue, Germany (Grünberg et al. 1999) or bitumen at sites in the Levant (Boëda et al. 1996), indicate the manufacture of composite tools, while stone tool assemblages in both Africa and Europe show increasing regional, chronological, and perhaps functional variation. Also on both continents, in Late Middle Paleolithic/MSA context, there appear bone tools like intensively-used awls (d’Errico et al. 2003) and bone points (Henshilwood et al. 2001), as well as the first instances of personal ornaments (Henshilwood et al. 2004) and the application of coloring material and decorative elements (Henshilwood et al. 2002). From around 0.1 Myr, there is evidence of intentional interment of human bodies; whether these qualify as burials and indicate symbolic behavior is still
under discussion. Finally, evidence of hearth structures, for example at Kebara (Meignen et al. 2001), mark a more habitual use of fire.

The Early Upper Paleolithic, starting at around 40,000 years and continuing until around 30,000 years ago, is characterized by intensified use of bone, antler, and ivory as raw material. In some regions of the world, a burst of personal ornaments and artistic representations is documented, e.g., rock art as in the French Grotte Chauvet (Valladas et al. 2001) and Australia or mobile art (Conard 2003) and musical instruments (Conard et al. 2004) in caves of the Swabian Alb. Although blades had been elements of the artifact inventories since the Lower Paleolithic, a new technological concept of blade production widely introduced in that period allowed an extended exploitation of the stone cores by optimizing the number of rather uniform blanks. In addition, Upper Paleolithic assemblages show increasing diversification in specific tool types for distinct purposes. Settlement of the European Arctic (Pavlov et al. 2004) and, most likely, of Japan took place in this time period; Australia had become inhabited slightly earlier (O’Connell and Allen 2004).

In the Middle Upper Paleolithic, from about 30,000 to roughly 20,000 years ago, the first unquestioned evidence of true burials with symbolic meaning, e.g., at Sungir (Pettitt and Bader 2000) and Dolní Věstonice (Klima 1988), are documented. Tool types became more and more standardized and regionally diversified. The period is known for an important extension of the find spectrum: evidence of fiber processing (Adovasio et al. 1998), systematic gathering of grass seeds (Piperno et al. 2004), production of unfired and fired clay sculptures (Klima 1991; Einwoegerer 2000), and, for the first time, construction of large and complex settlement structures mainly in the mammoth steppe, for example at Dolní Věstonice and Pavlov (Klima 1991). While depictions of animal–human hybrids and elements of the human body, like vulva signs and hand negatives, are known from the Early Upper Paleolithic, the Middle Upper Paleolithic introduced representations of entire human beings, which were extremely rare before and now became part of the parietal and mobile art spectrum in frequent Venus figurines, a few male images and some portraits. In this period, human occupation was extended to arctic Siberia (Pitulko et al. 2004).

The Late Upper Paleolithic, after the last glacial maximum, saw the introduction of complex tools that work only in combination with other artifacts like spear throwers with spears or needles with thread. A new category of artifacts, domesticated animals and plants, started to develop in human cultural contexts. Humans accompanied by the first domesticated animal, the dog (Sablin and Khlopachev 2002), migrated from Siberia to the Americas (Leonard et al. 2002), crossing the Beringian landbridge.
In conclusion, this brief outline, although only a superficial picture, demonstrates a gradual developmental process of progress, diversification, and intensification in archeological sites from 2.5 Myr ago until the end of the Pleistocene. It is important to note, however, that all observations of this period are biased by the decreasing chances, over time, of artifact conservation. Furthermore, summary views of large time periods and spaces may appear clear-cut but, if examined in detail, become blurred.

### 8.3 What could they do? Recovering the basis

Advanced tool behavior, as observed in great apes and the artifact record of *Homo*, is founded to only a minor extent on instincts—genetically based processes automatically released by key stimuli—and is instead derived from cognition. Thus, like all cognitively controlled behaviors, it can be stopped arbitrarily, altered by learning, and improved by experience.

The basis of cognitive behavior is the individual cognitive space (or mind), which can expand along three dimensions (Figure 8.2): the phylogenetic, the ontogenetic, and the historical-cultural. The phylogenetic dimension of an individual’s or a species’ mind expresses the genetic potential derived from evolutionary processes. Phylogenetic development in human cognitive evolution can be assumed, since great apes demonstrate marked differences in cognitive behavior, regardless of whether they grew up in an intact natural group of their own species or received individual cognitive support in a modern cultural-historical environment. The cause of this development in humans may be related to
physical features like the increase of relative brain size (McHenry and Coffing 2000) and possible changes in brain anatomy (Eccles 1989). Genetic studies suggest other or additional possible agents, like increased gene activity in the brain (Enard et al. 2002a) or the mutation of FOXP2, a gene involved in linguistic articulation (Enard et al. 2002b); their specific roles, however, remain unclear. The exploitation of the phylogenetic potential cannot ever be assumed to reach completion because it depends on the two other factors, the ontogenetic-individual and cultural-historical dimensions; therefore, even if two individuals or populations have the same phylogenetic cognitive potential, their cognitive performance as seen, for example, in artifacts may be completely different according to their cultural background and individual experiences.

The ontogenetic-individual dimension incorporates the cognitive elements originating in individual actions and experiences, be they accidental or intentional. This dimension is limited by the biological potential to think and act, given by genetic characters derived from phylogeny and is influenced by opportunities to interact with the environment. Behavioral innovations, which do not directly descend from genetic mutation, originate in this individual dimension. For the expression of the ontogenetic-individual dimension, the frame is set by the phylogenetic and the cultural-historical dimension, although individual performances may lie outside the population’s mean range which is normally extrapolated from archeological data.

The cultural-historical dimension, finally, expresses the culturally fostered factor of the mind, the cognitive dimension that is most prominent in and, in its full range, exclusive to humans. This dimension is opened by the spread of innovation in behavior, not by genetic transmission, between genetically related and unrelated individuals, within and between generations. On a low level of this cultural dimension, individuals adopt a certain behavior, whose outcomes they observe in others, by emulating it until they are personally content with the result. In a real cultural setting, however, with teaching and learning between individuals and shared attention on a problem, children do not have to find solutions on their own for problems that arise but can rely on culturally stored solutions, traditions, invented by individuals in past decades, centuries, or millennia. This historically grown solution set makes up a part of the individual’s environment that can be acted on and used as a basis for further innovation—the so-called Ratchet effect (Tomasello 1999). The cultural-historical dimension of the mind does not expand constantly; instead this dimension and with it the spread of innovations are strongly influenced by interdependent social parameters like intra- and intergroup communication, population density, social structures, the position of innovators in their groups, and general group-specific attitudes about
learning, innovation, and progress (Rogers 1995). Factors, such as communication, that may hamper or foster the increase of the cultural dimension have their origins partially in the phylogenetic dimension, probably with language faculty or the capability to understand others as intentional actors (Tomasello 1999).

In sum, the development of the human mind and the cognitive aspects materialized in artifacts should be viewed not as an exclusively phylogenetic process with some saltational breaks in its linear progress but as an exponential expansion in the three dimensions of cognitive space, the exploitation of which is incomplete and variable. Thus, early and rare or singular expressions of a capacity like symbolic behavior—in the Late Acheulian figurine of Berekhat Ram, for instance—can be seen as proof of the phylogenetic and ontogenetic ability of the actors at that time. As a communal trait within a specific cultural-historical context, these individual expressions may only be accepted and reproduced thousands of years later.

Cognition is the main basis of what prehistoric groups did, and this is partially expressed (Section Archeology as a paleoanthropological subject) in the artifacts that have been preserved to our times. Thus artifacts are a means for detecting the cognitive background behind their creation. This is not easy. Indications of prehistoric people’s cognitive potential—what they could think and do—have to be separated out from behavior compelled by the restrictions of the natural and social environment. Archeology can help to delineate the cognitive space of prehistoric groups and trace the development of the cognitive dimensions, especially the cultural-historical factor. Yet loss of evidence within the archeological record must also be factored in; it must be kept in mind that absence of evidence cannot be equated with evidence of absence and in not only material but also cognitive terms (Speth 2004). What we can detect in the archeological record is only a group’s minimum cognitive potential, which has been manifested in artifacts. Cognitive faculties that are apparently unexpressed in material remains because a group did not represent these faculties, or because an archeological analyst failed to recognize them, might have been present; yet researchers can only then state the lack of indication.

8.3.1 How to extract cognitive capacity and evolution from archeological remains?

The evolution of the human mind is an old question in paleolithic archeology (Verworn 1915). The flourishing of cognitive science (Varela 1990), beginning in the 1950s, did not touch the discipline’s potential, however: for a long time archeology and cognitive science widely ignored each other. While Leroi-Gourhan
(1964) sketched a singular developmental picture of the paleontology of human thought, most other archeological enquiries into cognition were predominantly raised to redefine human uniqueness, after widely recognized studies of animal tool behavior, documenting several animal species’ use of stones as tools (Hall and Schaller 1964; van Lawick-Goodall and van Lawick-Goodall 1966; Boesch and Boesch 1983) demonstrated that tool use could no longer be considered an exclusively human marker. The use of a tool to produce a tool, however, seems to represent, a specific human capability. This secondary tool use (Kitahara-Frisch 1993)—e.g., the use of a stone to alter another stone so it could be used to solve a specific problem—is a universal human trait for which there is only sparse and questionable evidence in chimpanzees (Sugiyama 1985, Takemoto et al. 2005). Today, regarding typically human cognitive performance and its origin, the focus in archeology has narrowed to so-called nonfunctional, symbolic artifacts related to “modern” human behavior as art, religious actions, and indirectly language, combined with planning and foresight (Noble and Davidson 1996; Mellars 1996; Klein 2000; Coolidge and Wynn 2001).

In fact, the wide disregard in Paleolithic archeology of the evolution of cognition is primarily based on the prevailing theoretical paradigms. New or Processual Archeology, while open to evolutionary approaches, considers cognition, with few exceptions, inaccessible to scientific analyses and testing. Postprocessual Archeology, although amenable to examining human thought in archeology, has rejected evolutionary approaches as simplistic, biologistic, disregarding of the cultural and individual bases of human behavior, and conducive to artifact assemblages which can hardly be generalized. Outside these mainstreams of late-twentieth-century archeological theory, there have been some attempts, described later, to approach cognitive evolution archeologically under the theoretical concept of Cognitive Archeology, whose approaches derive mainly from psychology.

### 8.3.2 Paleontology of human thought

One archeological attempt to illuminate the evolution of cognition appears in “La geste et la parole,” a pioneering work by French paleontologist and prehistorian André Leroi-Gourhan (1964), who saw the development of the modern human mind paleontologically as a process in which the physical evolution of the brain released new capacities for thinking. The early development of bipedal locomotion, for instance, not only freed the hands for technical actions but, with the shift of the foramen magnum, also enabled an increase in size of the occipital lobes. Subsequent simple technical solutions, like primitive stone tools, allowed
the reduction of the masticatory apparatus, which made further change in skull architecture possible; specifically, the parietal and especially the frontal lobes could gain their modern anatomical forms and structures, and the mouth, with decreased nutritional functions, could be used for vocal communication. Brain volume is of secondary significance to Leroi-Gourhan; besides the anatomical features of an upright posture, a short face and hands not engaged in locomotion, the main marker of humankind has been the manufacture and use of tools.

Leroi-Gourhan posits that human cognitive evolution was dominated by increases in technical intelligence and vocal capabilities, capacities that developed slowly until H. erectus, and then became more sophisticated, although still mainly technical, in Neanderthals. Only with the unfolding of the prefrontal cortex, bringing capacities for foresight, consciousness, the control of affect, and the ability to discern and thus to reflect on behavior, could late Neanderthals and, later, anatomically modern humans develop nonfunctional actions, symbolic capabilities, and creative consciousness. Thus, development was not bound solely to biological evolution, with memory encoded predominantly in the genes and with individuals inventing technical operations on their own. Rather, the new cognitive capacities fostered the ethnic group as a social memory pool with true language as a cultural storage facility, allowing the development of operational sequences in super-individual processes: in teaching and sharing problems and solution attempts with other members of the groups. The result was the explosion of artifact varieties and symbols in the Upper Paleolithic. In sum, Leroi-Gourhan’s focus lies on the physical basis of cognitive evolution with secondary support by archeological evidence. His model concentrates on the expansion of the phylogenetic dimension of cognitive space, with the cultural-historical factor becoming important only at the end of the Middle Paleolithic.

8.3.3 Early Homo capabilities in the light of Piaget’s theory

A second and completely different perspective on human cognitive evolution has been taken by Thomas Wynn (1979, 1981, 1985), who applied Jean Piaget’s model of ontogenetic developmental stages in children’s object behavior to Lower Paleolithic artifacts and thereby to human phylogeny. The first developmental stage, young infants’ sensorimotor intelligence, characterized by pure activity-based intelligence without inner representations of the actions, can also be observed in primate tool behavior; in this stage, activity cannot be reasoned out in advance. The second stage, preoperational intelligence, is marked by inner representations of single consecutive tasks, so that anticipation of the results of an
action is limited to the change in only one variable at time; planning of an action is therefore restricted to trial and error. Wynn (1981) has identified this stage in chimpanzee tool manufacture, as well as in the simple technology of Oldowan core tool assemblages (for the problems of Oldowan interpretation see (8.2)).

The next stage, the concrete-operational phase, allows coordination of changes in several variables. It is now possible to anticipate the result of an operational sequence or to construct the operational sequence for reaching a desired result, so complex planning can proceed, and errors can be envisioned and corrected before they are executed. This concrete-operational stage, which according to Piaget should be fully developed by age 11–13, is identified by Wynn (1979) in the bifacial technology of Acheulian hand axes. Diverging from Piaget (1970), who differentiated between concrete-operational intelligence in children and the formal-operational intelligence that succeeds it in modern adults, Wynn merges these two stages and concludes that human phylogenetic development of cognition—as it can be seen from technological perspective—reached modern competence around 300,000 years ago, at the latest. Although Wynn’s interpretation needs reevaluation in light of challenges to Piaget’s theory by modern psychology, his attempt to adapt an object-directed psychological theory to archeological analysis of artifact traits is a positive example for future studies.

8.3.4 Looking for the origin: Toward primate archeology

A third means used to illuminate the phylogenetic dimension of the cognitive basis of early human tool behavior has been to make comparisons with ape performance. In the last years, the knowledge of tool behavior in great apes has markedly broadened through research on chimpanzees Pan troglodytes (McGrew 1992; Whiten et al. 1999) and orangutan Pongo pygmaeus (van Schaick et al. 2003), as well as on the less-observed bonobo Pan paniscus (Hohmann and Fruth 2003). Probable cultural differences among groups have been compiled and correlated with complex object-behavior, and these data have expanded archeologists’ view of the range of culturally influenced behavior and artifact categories not preserved in archeological context. As noted previously, however (Section Definitions), primatological results answer archeological questions about basic object behavior only partially.

To fill this gap, which is especially critical with regard to stone tool technology, experiments have been designed to examine motor and cognitive abilities in stone flake production. While early testing with an orangutan (Wright 1972) had a behavioral focus for understanding the functional aspects of cutting tools, the long-term experiments with bonobo Kanzi (Toth et al. 1993; Schick
et al. 1999) have been planned in cooperation with archeologists and observed from a technological perspective. Kanzi proved able to detach flakes from a core with a hammerstone, although he preferred to produce cutting edges by throwing a stone on a hard surface, a technique he invented himself. After 3 years of knapping experience, Kanzi could still not flake efficiently by exploiting acute angles on the core, a method regularly observed in Early Lower Paleolithic context (Roche et al. 1999).

Archeologists have also analyzed and compared the stone tools at a chimpanzee nut-cracking site with Oldowan assemblages (Mercader et al. 2002). These comparisons suggested that, despite previous doubts (Wynn and McGrew 1989), morphological analysis could clearly discriminate between human tools flaked intentionally and chimpanzee artifacts produced as a chance result of other activities with stones. Primate archeology is still in its beginnings and has not yielded any model of human cognitive evolution; nonetheless, it is another promising approach for taking a detailed look at the specificity of human tool behavior.

8.3.5 From domain-specific intelligence and to a fluent mind

A fourth approach has been developed by Steven Mithen (1996), who, based on psychological models of different cognitive domains in modern humans, has created a hypothetical model of the phylogenetic development of human cognition. Mithen identifies four distinct domains of intuitive intelligence in modern children that, he believes, reach back to Pleistocene times: linguistic, social, technical, and natural history. Only when these types of intelligence are combined can the knowledge specific to one domain be generalized to the other domains and made usable beyond the circumstances in which it arose, enabling creativity to develop. Analyzing the technical and environmental behavior of modern chimpanzees, as well as the assumed behavior of the common ancestors of humans and chimpanzees, and assessing that both originate in a basic general intelligence domain, Mithen detects in these species only one specialized domain, social intelligence, which he believes became fully developed in early Homo at around 2 Myr. In his opinion, the technical and natural history domains arose sometime up to 1.8 Myr and allowed the Homo genus’ expansion out of Africa and spread to large parts of the Old World. For the following 1 Myr, mental organization did not show major changes, paralleling a trend of stagnation in relative brain growth. Mithen expects that linguistic intelligence came into being between 0.5 and 0.1 Myr but was initially bound to social intelligence; he assumes that technical and environmental issues could not be talked about at that time.
because these issues were still encapsulated in their own domains. A cultural explosion took place between 60,000 and 30,000 BP, when, according to Mithen, the knowledge stored in specific intelligence domains became accessible to the other domains. This cognitive fluidity is evidenced in archeological artifacts like bone and antler tools, blade technology, grave goods, the expansion of occupation to Australia, personal ornaments, and art—all of which require a combination of knowledge from social, linguistic, technical, and natural history domains. This model, while provocative, consists of open generalizations that fail to account, for example, for how the Late Acheulean wooden spears from Clacton or Schönningen could be manufactured before the development of a cognitive synthesis. Thus, Mithen’s model of distinct intelligence domains becoming fluent on the eve of modern behavior can be summed up as adapting hypotheses from evolutionary psychology to human cognitive evolution by matching them in a speculative way to selected parts of the archeological record.

8.3.6 Language and symbolic behavior as milestones of cognition

In a fifth prospective on the cognitive basis of early human tool behavior, Noble and Davidson (1996) erect a phylogenetic model of human cognitive development on the premise that, unlike chimpanzees, modern humans can share their awareness of objects and events, to which they can give socially constructed meaning with the help of language. Their research starts with observations of aimed throwing as the hypothetical germ of pointing, a primeval mode of sharing awareness intentionally. Aiming or pointing, they posit, could have developed into iconic, representational gestures that, in their repetition, could have left chance traces on some material. Once recognized and imitated as representatives of the gesture, these signs might have become symbols; and once the principle of representing symbols was understood, the faculty of language might have arisen as a result of the shared meanings. Language, then, allowed ways of thinking which had been impossible without it: it permitted the description of perceptions, reflections, memories, plans for the future, and awareness of oneself as part of the world and as a perceptive individual. To support their speculative model of the development of shared assignment of meaning through language, Noble and Davidson look for evidence of symbolic behavior and planning in archeological remains. Up to and including the Middle Paleolithic, they find that no specific artifact forms were produced in a goal-directed process and that the observed progress is only technological, not conceptual. For the authors, however, Upper
Paleolithic art and the colonization of Australia by boat are the most prominent among the first markers of modern cognitive aspects which derive from language, constituting true manifestations of symbols, and planning. This model, again, constitutes an attempt to parallelize ideas derived from psychology with some selected artifacts and events in prehistory. Yet this has been done in a rather imaginative way basing more on common knowledge than on strict theoretical discussion and without an empirical analysis of the distinctive traits of artifacts chosen from the archeological data set to support or disconfirm the hypothesis.

8.3.7 Increasing the problem-solution-distance

A sixth approach to human cognitive evolution on the basis of tool behavior focuses on a particular attribute of artifacts: the dissociation of problems and solutions. In his famous experiments, especially with chimpanzees, in the early twentieth century, Köhler (1963) recognized tool behavior as an extension of the process of round about thinking. If tool use is considered to solve a problem, then the immediate desire, to get a fruit for example, has to be set aside for one or several intermediate objectives such as finding or producing an appropriate tool. Thus, at least in the short term, thinking and resulting physical actions must depart from the immediate problem. Separated from each other, the different elements of mental or physical operations may not seem to be useful; if one is unable to conceptualize a tool for termite-fishing, it does not make sense to look for a thin and flexible twig in the bushes 5 m away from the termite mound. However only in the combination of these different operational elements, the final aim can be reached. In essence, thinking shifts from the immediate givens of a problem to abstract conceptualizations of possible solutions and sequences of means, necessitating appropriate tools, for achieving these solutions in the future. The more that tools and their manufacture can be dissociated from immediate subsistence aims, the more problems become soluble. In handling artifacts, humans are able to speculate on the thinking that may have guided the artifacts’ manufacture and original purpose as well as to think about possible improvements in the tools and adaptations to other problem contexts. Thus, tools can not only be used mechanically but also serve as cognitive instruments in metareflections—in past as well as future directions. By producing tools, humans do more than just make the environment increasingly manageable; they also create a material and cognitive world on their own, which expands with the increasing dissociation of subsistence constraints, perceived problems, and available solutions.
An increasing dissociation of problems and solutions, as well as an expansion of the range of problems perceived beyond subsistence, can in fact be observed in the development of human artifact behavior (Haidle 2000, 2004, 2006). In Oldowan context, the transport of raw material over some kilometres and the use of secondary tools (tools produced by employing tools to solve a problem) both indicate an awareness that problems may require a phased solution over time, and that provision must be made in the present for solving problems in the future. Extended operational sequences, which must follow a consecutive although not necessarily strict plan, can be observed in bifacial technology, assuming that the knapping of bifacial tools represents the shaping of an intentional form. Further, a marked extension of production time and use of tertiary tools—that is, tools manufactured by the use of a secondary tool—is present in Lower Paleolithic wooden spears, for example, since a stone tool had to be prepared as an intermediate instrument to carve these means for hunting.

In so-called nonfunctional, symbolic tools, such as art objects and ornaments, the link between problems and solutions becomes exclusively conceptual. Additionally, the problems these tools solve go beyond individual needs to challenges relevant to the social community. With the help of true symbolic tools as communication devices, information can be transferred by the mere existence of these artifacts in a certain context without any further action of their creator. An additional expansion of the problem–solution distance becomes evident in organized trade and specialization on selected activities: solutions are offered for other people’s needs, a behavior which is in the following extended to abstract needs of unknown customers. In short, the range of problems addressed widened slowly over time from direct and personal physical problems to indirect, superindividual, abstract, and cognitive problems, culminating today in products like computers, whose elements, produced independently all over the world, receive their problem-solving power only in combination.

The origin of this phenomenon of an increasing dissociation between subsistence, perceived problems and activities generated to solve them cannot be assigned to one genetically based character alone, but must result from the expansion of the cognitive space in all three dimensions, the phylogenetic-biological, the ontogenetic-individual, and especially the cultural-historical which fosters the cultural storage of solutions. Due to the complex interactions of the three cognitive dimensions with the phenomenon of increasing problem–solution dissociation, the extension of this dissociation accelerates exponentially in its developmental history. This may be at least one reason why only a few, slow changes can be observed in early artifact assemblages, compared to more frequent changes in later artifact history.
8.4 Conclusions

Through the study of artifacts, archeology provides an insight into tool use as a major part of human behavior. Five facets of archeological knowledge can be drawn from the material remains of object-bound activities: typological, technological, functional, contextual, and cognitive information, from which other behavioral aspects, like subsistence, settlement, social organization, and their cognitive background, can be derived. The only available evidence, although fragmented, on the development of human behavior comes through diachronic comparison of artifact assemblages; and thus, questions of how prehistoric populations used their cognitive potential, composed of phylogenetic-biological, ontogenetic-individual, and cultural-historical dimensions, can be approached only through archeology. The study of the evolution of the human mind is still at its beginning, however. Some archeological investigations of human intellectual development set up cognitive traits linked with tool behavior and try to find them in the archeological record, while others take hypothetical psychological models without clear links to tool behavior and try to match them with selected artifacts and events in prehistory. But until the signal strength of archeology, the analysis of tool-related behavior, is integrated into models of human cognitive evolution, these models will remain speculative.

9 Contribution of Stable Light Isotopes to Paleoenvironmental Reconstruction

Julia Lee-Thorp · Matt Sponheimer

Abstract

In this chapter, we focus attention on the potential linkages between hominin evolution and environmental change in Africa, as shown by the stable light isotope evidence. We begin with an overview of the principles and the materials typically available to produce this kind of stable isotope data. Carbon isotope analyses of faunal enamel, soils, and ostrich eggshells provide good evidence for the emergence of C_{4} grasses ca. 5–8 Ma, broadly concordant with hominin bipedalism. Although C_{4} grasses remained a modest yet variable component of the vegetation for millions of years, the associated biomass may have quickly become an important foraging resource for hominins. Rather than a climate-driven “pulse” ca. 2.4–2.8 Ma, evidence from East and South Africa suggests a significant change to more open, grassy ecosystems ca. 1.8 Ma, broadly concordant with the emergence of early Homo. On present evidence, there appears to be only a weak overall aridification trend for the entire period from ca. 4 Ma. Speleothem and other evidence points to deep-rooted cyclicity in floral and rainfall shifts, which suggest that obliquity and precessional orbital cycles were important drivers of environmental variability. In relation to climate and environmental influences on hominin evolution, a revised “Savanna” hypothesis may yet be compatible with the “variability selection” hypothesis.

9.1 Introduction

It is widely accepted that understanding the environments that hominins inhabited provides important information for understanding evolutionary trends. First, and perhaps most obvious, we need this contextual information to tell us about the kinds of opportunities available for the basics of life–food,
water, and shelter, and the biological and perhaps cultural responses used to obtain these things. Second, there are questions about how environmental and climate shifts might have influenced the course of hominin evolution and, similarly, that of other coeval fauna. Here, paleoenvironmental studies must take a broader, more long-term view. Large-scale, global climate shifts are very often invoked as major influences on evolutionary pathways, but in practice demonstrating the links is not at all straightforward (Feibel 1997). This is partly because of the nature of the environmental evidence on land, which is patchy in time and space and often poorly dated, and partly because climate is just one of a number of forces acting on landscapes.

One of the ways to address this problem is to take a broad, continent-based perspective that can “subtract” more local environmental influences. At the same time, we must bear in mind that behavioral (and biological) responses of hominins occur at the local level, which is the most important for understanding the lives of individuals. In other words, scale is important, depending on the question that is being asked. In this chapter, we focus our attention on paleoenvironments of Africa for the obvious reason that much of early hominin evolution occurred there.

A whole range of investigative tools is available for reconstructing paleoenvironments at the site level. Standard methods rely on geological context, faunal abundances, and in some cases floral indicators such as woody materials or pollen. None of these approaches on its own is sufficient because each has its own set of advantages and disadvantages. For instance, methods based on vertebrate faunal-abundance data have to rely on what is deposited, preserved and found in a site so that the fossil bones represent a highly filtered representation of the original vertebrate fauna. Furthermore, in interpreting abundance data as environmental proxies, one has to rely on knowledge of the habitat requirements of various animals, and this is difficult for unfamiliar, extinct taxa. In fact, we very often do not understand enough about the habitat requirements of their modern relatives (Cerling et al. 2003; Sponheimer et al. 2003). Stable isotope approaches can help to provide this complementary evidence.

There are even greater challenges in reconstructing evolving continental climates and landscapes beyond the site level to regional or global contexts. They are partly related to the enormous heterogeneity of continental environments, and partly to the rarity of long, continuous records on land. To this is tied a problem of chronological control. Global climate changes are mainly understood from marine sediment cores that provide an oceanic perspective on climate evolution (Zachos et al. 2001), but it is not always clear how these changes have affected continental African environments. Moreover, it is unclear whether
large-scale climate shifts are synchronous across the continent; between the north and south, and east and west, many recent and ancient climate fluctuations are thought to be opposite (or antiphased) (Nicholson and Entekhabi 1986; Partridge et al. 1997; Tyson et al. 2002). Continuous marine sediment records near continental margins have provided some direct information about African climates. For instance, episodes of windblown dust off North Africa indicate increasing Saharan aridity from ~2.6 to 2.8 Ma (deMenocal 1995), and entrained pollen indicates the pattern of contraction and expansion of West African equatorial forests in the Late Pleistocene (Dupont 1999). These patterns, however, are not necessarily representative of trends for East and southern Africa, where most of the hominin sites are found. Thick sedimentary sequences with diatomites and other organic derivatives from continental lake systems provide good proxies for lake histories and salinity, but they are extremely discontinuous in space and time. For instance, deep, old, but discontinuous lake systems are known from the East African Rift, while none occur in southern Africa. Lake formation is dependent both on basin formation, defined by tectonic activity, as well as on a positive precipitation/evaporation balance, controlled by climate (Trauth et al. 2005). Other land-based clues come from pollen (Bonnefille 1983, 1995) and faunal abundance data considered regionally (Vrba 1985, 1988; Behrensmeyer et al. 1997; Reed 1997; Bobe et al. 2002). Vrba’s “turnover-pulse” hypothesis that postulates a direct link between evolutionary trends in bovids and climate shifts at ~2.4–2.6 Ma (Vrba 1985) was based on bovid abundances, while studies that tested or disputed this idea were based on consideration of radiations among a broader range of fauna (Behrensmeyer et al. 1997; Bobe et al. 2002).

Stable light isotope tools can help to address some of the gaps. These biogeochemical tools have several advantages, because once the principles of isotope fractionation in biogeochemical pathways are understood, they may be broadly applied to past ecosystems to produce quantitative, repeatable results. Stable light isotope applications to paleoenvironmental reconstruction have been extensively reviewed in the literature and the field is broad (for a global review see Koch 1998). Given the breadth of the topic, our intention here is to restrict discussion to some of the key examples that we believe have made, or look set to make, substantive contributions to understand the environments associated with hominin evolution. These contributions lie principally in the context of shifts in floral composition (such as the relative abundance of C4 grasses in the flora, and implications for climate) and climate indicators including temperature, aridity, and seasonality. The nature of longer-term climate evolution can be deduced from these data. We concentrate on examples reliant on materials from hominin or paleontological sites, or from sequences that are closely associated in space and time.
9.2 Isotopic environmental indicators

This section provides a brief overview of the main isotopic environmental indicators and the sample materials that are used to provide indications of prevailing conditions. It is important to understand these principles as they apply to each potential archive, as they are all likely to provide slightly different perspectives, and in order to evaluate the quality of the evidence.

9.2.1 Basis of stable isotope tools

The stable light isotopes of principal interest as environmental proxies are the isotopes of hydrogen, carbon, nitrogen, and oxygen. In all cases, the chemistry of the different isotopes of an element remains the same as chemical properties are controlled by electron configuration. Among these light isotopes, the mass difference owing to one or two extra neutrons is sufficient to cause a small, but predictable, difference in the rates of chemical reactions or physical processes. If the starting materials and the products of a reaction are partitioned in some way, observable isotopic fractionation occurs.

9.2.1.1 Hydrogen (D/H) and oxygen (\(^{18}\)O/\(^{16}\)O) isotope fractionation

Fractionation of hydrogen (D/H) and oxygen (\(^{18}\)O/\(^{16}\)O) isotopes\(^1\) in nature follows similar patterns because their isotope effects are dominated by the processes undergone by water evaporation, condensation, and freezing. The magnitude of fractionation is controlled largely by temperature in both cases, but isotope effects are much higher for hydrogen because of the greater relative mass difference between deuterium (D or \(^2\)H) and hydrogen (\(^1\)H) compared to oxygen (\(^{18}\)O and \(^{16}\)O). Water vapor evaporates largely from low- to midlatitude ocean surfaces, and sea surface temperature (or latitude as a proxy) of the oceanic source influences isotopic ratios of moisture-laden weather systems (Dansgaard 1964). Further influences on the isotopic composition of rainfall occur during subsequent

\(^1\)Isotope ratios are expressed by convention in the \(\delta\) notation, in parts per thousand (‰) relative to a standard: \(\delta X (\%) = (R_{sample}-R_{ref})/R_{ref} \times 1000\), where \(R\) is the isotopic ratio. V-SMOW (Standard Mean Ocean Water) is used as the reference for D/H and \(^{18}\)O/\(^{16}\)O in water, V-PDB (Peedee Belemnite) for \(^{18}\)O/\(^{16}\)O and \(^{13}\)C/\(^{12}\)C in carbonates and organic materials, and atmospheric N\(_2\) (AIR) for \(^{15}\)N/\(^{14}\)N.
transport of these weather systems across continents, related to factors such as the
distance traveled, mountains crossed, and height and temperature of rainclouds
(Dansgaard 1964; Rozanski et al. 1993). A further effect in arid landscapes is due
due to evaporation. Soil- and groundwater isotope values reflect this history, as do
carbonates precipitated from these waters, with the additional influence of local
temperature as fractionation during carbonate precipitation is temperature depen-
dent. This is the basis of the familiar “temperature equation” applied to many
carbonates (e.g., forams, corals, and speleothems) (McCrea 1950). In addition,
isotope effects also occur in plants. A large isotopic enrichment occurs during
daytime evapotranspiration in plants under hot, dry conditions (Yakir 1992).

9.2.1.2 Carbon ($^{13}$C/$^{12}$C) isotope fractionation

Carbon ($^{13}$C/$^{12}$C) isotope fractionation provides fundamental information
about pathways in the terrestrial carbon cycle (see also Sponheimer and Lee-
Thorp Vol. 1, Chapter 17). A large depletion in $^{13}$C occurs during assimilation of
atmospheric CO$_2$ in photosynthesis, but to different degrees depending on the
photosynthetic pathway (Smith and Epstein 1971). C$_3$ plants (trees, shrubs and
forbs, and temperate or shade-adapted grasses) are more depleted in $^{13}$C and have
low $\delta^{13}$C values, while C$_4$ plants (mainly tropical grasses) are less depleted
(\textit{Figure 9.1}). A smaller group of succulent plants follow the Crassulacean acid
metabolism (CAM) pathway, which essentially alternates use of these two path-
ways by night and day, and depending on conditions, so that their isotopic
compositions vary considerably. These plant values are archived in slightly
different ways in a range of sample materials (\textit{Figure 9.1}).

9.2.1.3 Nitrogen ($^{15}$N/$^{14}$N) isotope ratios

Nitrogen ($^{15}$N/$^{14}$N) isotope ratios reveal pathways in the nitrogen cycle, but since
the pathways are complex, the values observed between different ecosystems are
highly variable. Nitrogen enters the terrestrial foodweb via N$_2$-fixing bacteria in
soils or plants to form nitrates or ammonium ions that are utilized by plants. The
net effect of this biological nitrogen fixing and subsequent nitrogen loss is a slight
enrichment in $^{15}$N, but the balance and mode of fixing and loss is strongly
affected by environmental conditions (Heaton 1987). In a global survey, Handley
et al. (1999) found a negative correlation between moisture availability and both
leaf and soil $\delta^{15}$N. Stepwise trophic enrichment of about 3–5‰ occurs in animals
because there is an $\sim$3‰ fractionation between diet and tissues. The trophic
effect, however, can be surpassed by enrichment associated with environmental aridity (Heaton et al. 1986; Sealy et al. 1987; Johnson et al. 1997), effects that are certainly related to raised leaf and soil values in arid areas (Heaton 1987). The effect is very marked in animals living in areas with $<400$-mm rainfall/annum, so $\delta^{15}N$ can be an indicator of aridity.

### 9.2.2 Sample materials

The sample materials most often used as environmental indicators in sites associated with hominin activities consist largely of bones and soils in close chronostratigraphic association with those sites. Fossil ostrich eggshell and cave speleothems represent promising but more rarely explored sources of paleoenvironmental and climate information.

#### 9.2.2.1 Bones and teeth

Bones are abundant in most sites where conditions are conducive to preservation. They conserve information about many of the processes and conditions to which the animal was subjected when it was alive, which can be accessed via their stable light isotope compositions. Bones and dentine consist of about 25% (by weight)
of a fibrous protein, collagen, and about 75% embedded bioapatite mineral. Collagen can be relatively easily purified and analyzed for δ^{13}C and δ^{15}N. However, it tends to decompose over time so that by about 10–20 Ka collagen has all but disappeared from bones and teeth in most African sites (preservation is better in cool Eurasian sites). The mineral is composed of calcium phosphate crystals with many other ions substituted into the structure (LeGeros 1991) that tend to increase their reactivity and solubility. One exception is fluoride, which enhances stability. Substitutions also affect how well bones and teeth are preserved as fossils. Enamel is far more stable than bone apatite (Lee-Thorp and van der Merwe 1987) and consequently most isotopic studies of fossil fauna have relied on enamel as sample material. The component ions of interest are phosphate (PO_4^{3–}) and carbonate (CO_3^{2–}), with the latter occurring in small amounts (3–6%) as a substitution. Therefore, the isotopes available for study in this system are carbon and oxygen isotopes, and the latter may be extracted from either PO_4^{3–} or CO_3^{2–}.

Bioapatite phosphate δ^{18}O has been developed as a paleotemperature tool, based on the rationale that body water δ^{18}O (δ^{18}O_{bw}) in mammals is related to environmental or drinking water (δ^{18}O_{w}), which can in turn be correlated with latitude and temperature effects on rainfall (Longinelli 1984; Luz and Kolodny 1985, 1989). In low- to midlatitudes, temperature effects are far less important than storm-track and amount effects on δ^{18}O of environmental water plus isotope effects on plant waters. We now know that animal behavior, related to drinking patterns and/or thermophysiology, can modulate these environmental signals considerably (Bocherens et al. 1996; Kohn et al. 1996; Sponheimer and Lee-Thorp 1999b, 2001) and that these patterns are conserved in fossil assemblages. Ayliffe and Chivas (1990) found a correlation between δ^{18}O_{PO4} and relative humidity in non-obligate drinking animals—in their case, kangaroos, so that these behaviors might still provide useful environmental data. In order to circumvent the problems of variable responses to climate factors, many authors have relied upon “well-behaved,” obligate drinking species such as equids for extracting paleoclimate proxies (Sánchez-Chillon et al. 1994; Bryant et al. 1996).

Stable carbon isotope (δ^{13}C) analysis of herbivore tooth enamel (or collagen) indicates the relative amounts of C_3 plants and C_4 grasses consumed. The calculations are based on our understanding of typical plant values today and how they might be affected by climate variables, and by the difference between diet and enamel δ^{13}C values (or Δ_{diet-en}). There is a little “play” here, since C_3 plants may be slightly enriched in ^{13}C under hot, arid conditions, and vice versa. C_3 plants in dense forests, where a “canopy effect” with recycling of CO_2 and low light prevails, are typically depleted in ^{13}C (van der Merwe and Medina 1989, 1991). Alterations in the species composition of C_4 grasses, in response to conditions, may shift their average δ^{13}C value slightly (by perhaps 1‰).
In addition, $\Delta_{\text{diet-en}}$ is not precisely established; some authors observe $+12\%$ (Lee-Thorp and van der Merwe 1987), while others have observed up to $+14\%$ (Cerling and Harris 1999). Still, these small differences make no practical difference to distinguishing between C₃ and C₄ consumers since these $\delta^{13}C$ distinctions are large (Figure 9.1). The presence of C₄ grazers in an assemblage allows us to deduce presence of tropical C₄ grasses in a landscape. Although this information alone may be useful, for instance, if a shift between cold- and warm-season rain patterns is suspected (Lee-Thorp and Beaumont 1995), in practice we need to take this process further. Usually we require information about how closed or open vegetation cover was. A C₃/C₄ index has been developed to reflect the relative openness of an environment from $\delta^{13}C$ data in a faunal assemblage (Sponheimer and Lee-Thorp 2003) (see below).

9.2.2.2 Ratite eggshells

The eggshells of ostriches and earlier ratite taxa are durable and often abundant in paleontological and archeological sites. The shells consist of a protein matrix and inorganic calcium carbonate. Eggshells can yield $\delta^{13}C$, $\delta^{15}N$, and $\delta^{18}O$ proxy information reflecting conditions during the short egg-laying season. Ostriches are mixed feeders that prefer tender plants, which can include succulents as well as annual grasses and forbs in their diets; hence $\delta^{13}C$ data can indicate presence of both C₄ grasses and CAM plants (Stern et al. 1994; Ségalen et al. 2006). The $\delta^{15}N$ values are thought to reflect mean annual rainfall (MAP) (Johnson et al. 1997) in the same way as mammals in arid regions with under 400-mm rain/year (Sealy et al. 1987). $\delta^{18}O$ data also reflect aridity but from a slightly different perspective; since ostriches are drought-tolerant animals that do not need to drink free water, $\delta^{18}O$ primarily reflects leafwater enrichment due to evapotranspiration under hot, dry conditions (Lee-Thorp and Talma 2000). Because of the high variability in $\delta^{18}O$ and $\delta^{15}N$ data, large numbers of analyses are required (Lee-Thorp and Talma 2000). To date, only one study has produced a sequence, extending beyond the Holocene based on all three proxies (Johnson et al. 1997).

9.2.2.3 Soils

A history of overlying vegetation may be preserved for long periods in remnant organics and pedogenic carbonates in paleosols (Cerling et al. 1991). The principles are by now familiar: carbon isotopes in both the organic and inorganic components
of soils systematically reflect differences between vegetation following the C\textsubscript{3} and C\textsubscript{4} pathways, allowing estimations of the relative mix of woody and grassy plants on the landscape. $\delta^{13}C$ of paleosol organic matter, where preserved, is a reasonably direct reflection of the mean isotopic composition of the vegetation, with a small enrichment in $^{13}C$ owing to decomposition and associated processes (Cerling et al. 1991). Pedogenic carbonate nodules are formed about 0.5–1 m below the active soil horizon from soil-respired CO\textsubscript{2} (Cerling and Quade 1993). There is a net enrichment in $^{13}C$ of 14–17‰ due to combined effects of diffusion and isotopic fractionation during carbonate precipitation, causing increases of 4.4–5‰, and 9.5–12.5‰, respectively (Cerling et al. 1988, 1991; Cerling and Quade 1993). Pedogenic carbonates have a relatively restricted distribution; for one, nodule formation is associated with semiarid to arid conditions. An important constraint is the identification of “true” pedogenic nodules formed well below the active, identifiable soil horizon, where diffusion enrichment is complete and there is no mixing with atmospheric CO\textsubscript{2} (Cerling et al. 1988; Cerling and Quade 1993).

9.2.2.4 Cave speleothems

Cave flowstones and stalagmites are composed of calcium carbonate formed from CO\textsubscript{2}—rich seepage water dripping into cave systems, degassing, and precipitating as carbonate. Their $\delta^{13}C$ and $\delta^{18}O$ values reflect the proportions of C\textsubscript{3} and C\textsubscript{4} plants in overlying vegetation, and the isotopic composition of the water, in a similar manner to pedogenic carbonates. Speleothems have some decided advantages. For one, a closed cave system is a protected environment, where averaged annual temperatures are maintained year-round, along with high relative humidity. In a closed cave system equilibrium conditions are more likely, meaning that greater confidence can be placed in the isotopic data as sound indicators of environmental conditions. Very importantly, they are incremental structures and can be precisely dated using thorium–uranium disequilibrium or lead isotopes. Ages are more difficult to obtain for older Pliocene- or Miocene-age speleothems, but paleomagnetic and lead–uranium methods are being developed (Hopley 2004). So, where the right material can be located and the ages determined, speleothems can be sampled at small intervals to yield continuous, high-resolution records of a quality unlike any of the other proxies discussed here. Continuous sequences like this are invaluable because they can be compared with other dated continuous records, and they allow us to check trends and the scales of variability.

The following section describes some important applications of isotopic tools to paleoenvironmental and -climate problems.
9.2.3 Emergence of C₄ grasses

One important application has been to document the global expansion of C₄ grass systems between ~8 and 5 Ma (Cerling et al. 1997; Jacobs et al. 1999). Since both biochemical and fossil evidence suggest that our common ancestor with chimps lived at about this time, this important environmental shift might well have had some direct impact on the origins of the hominin lineage. The phenomenon was first detected in pedogenic carbonate nodule isotope studies from East Africa and Pakistan (Cerling et al. 1988; Quade et al. 1989; Cerling and Quade 1993). In East Africa, Cerling et al. (1988) observed the first appearance of C₄ grasses in the Turkana Basin ca. 7 Ma. This pattern of first appearance of significant amounts of C₄ has been mirrored in δ¹³C of fossil fauna in Africa, North and South America, and Pakistan (Cerling et al. 1997), although Fox and Koch (2003) have suggested earlier presence of minor amounts of C₄ biomass in the North American Great Plains, based on pedogenic carbonate evidence. Kingston et al. (1994) and Morgan et al. (1994) have argued that modest proportions of C₄ grasses were present earlier in the Mid-Miocene of East Africa, based respectively on continuous heterogeneity in a pedogenic carbonate sequence from the Tugen Hills and several slightly enriched faunal values from early Tugen Hills sites. The argument hinges largely on the weight of evidence, since the results for the Tugen Hills pedogenic sequence have not been replicated elsewhere in Africa. The values used to demarcate the certain presence of C₄ in fauna also differ as Morgan et al. (1994) used a value of -10‰ as the cut-off point, above which they deduced presence of C₄, whereas Cerling et al. (1997) used a more conservative -8‰.

Most evidence, however, still suggests that C₄ grasses first began their expansion in lower latitudes at ca. 7–8 Ma, expanding over the next few million years to midlatitudes (Cerling et al. 1997). The timing is unclear in southern Africa. Ratite eggshell data document emergence of C₄ and differentiation of the δ¹³C records between the southern and northern Namib about 5 Ma (Ségalen 2003; Ségalen et al. 2006). A large undated, collapsed cone speleothem in the Makapansgat Limeworks in South Africa indicates relatively invariant C₃ vegetation cover from the δ¹³C record, suggesting that it was formed prior to C₄ grasses reaching this region at ~27°S (Hopley 2004). A notable exception to the general picture of C₄ expansion is the 5-Ma-year-old site of Langebaanweg in the southwestern Cape of South Africa (Franz-Odendaal et al. 2002), where faunal δ¹³C data show that a winter-rainfall, Mediterranean-type ecosystem was already in place in this region in the Late Miocene and Early Pliocene. In the northeastern interior, faunal evidence suggests a minor presence of C₄ vegetation by ~4 Ma or earlier from the Rodent Corner at Makapansgat Limeworks (Hopley et al. 2006), while the modest proportion of pure C₄ grazers in the Makapansgat Member 3
faunal assemblage indicates clear presence by $\sim$3 Ma (Sponheimer and Lee-Thorp 1999a).

The expansion of C$_4$ grasslands across large parts of the world must have a global driver but the exact causes have remained curiously elusive. Cerling et al. (1997) and Ehleringer et al. (1997) proposed that plummeting CO$_2$ levels in the Late Miocene, to a level below 500 ppm, favored C$_4$ plants. The hypothesis is based on the known tolerance of C$_4$ plants for lower levels of $p$CO$_2$. But evidence from marine cores suggests that CO$_2$ levels were already low prior to this period (Pagani et al. 1999). This, along with $\delta^{13}$C data from fossil ratite eggshells in Namibia that closely track the marine-derived trends in $p$CO$_2$ for the Miocene (Ségalen et al. 2006), has lead to a reconsideration of the possible drivers. The emergence and spread of C$_4$ may reside in a combination of tectonic and solar insolation forces that rearranged the earth’s global heat budget, both spatially and seasonally. Resolution of the problem likely requires a good deal of more detailed evidence from the transition period, spread across different regions of Africa and elsewhere.

### 9.2.4 Evolution of open African environments

A great deal of interest has been shown in issues related to the decline of large-scale forests and opening up of the African landscape. Some years ago, the “Savanna hypothesis” held that forest shrinkage/savanna expansion in Africa was a primary driver of hominin bipedalism because it was thought that these two trends occurred at about the same time. This hypothesis fell from favor once it became apparent that bipedalism emerged before 5 Ma among relatively wooded habitats (WoldeGabriel et al. 2001). Nevertheless, there have undoubtedly been important and influential changes in the vegetation structures across Africa. Vrba’s turnover-pulse hypothesis relied on the observed radiation of open-country grazing bovids to draw inferences about shifts to more open landscapes in the Pliocene and Pleistocene, which could be linked to hominin evolutionary changes (Vrba 1980, 1985, 1988). This approach is not entirely straightforward because the habitat preferences of extinct bovids, or indeed of any extinct animals, are not always clear. Vrba proposed that a shift to bovid lineages with open-country preferences between about 2.4 and 2.6 Ma was associated with the onset of Northern Hemisphere glaciation observed from marine oxygen isotopes in marine sediment core records (Shackleton et al. 1984). But the nature of the climate trigger is not clear. The idea of a pulse in faunal change has been challenged, although it is acknowledged that faunal changes occurred between 2 and 3 Ma (Behrensmeyer et al. 1997; Bobe et al. 2002).
Further perspectives on the appearance of savanna landscapes have emerged from several isotope studies. Although C₄ grasses appeared in the Late Miocene and persisted with fluctuations through the Pliocene (Cerling et al. 1988; Cerling 1992; Kingston et al. 1994; WoldeGabriel et al. 2000; Wynn, 2004), importantly, they did not become a consistently dominant part of the floral biomass until ∼1.8 Ma (Figure 9.2). A shift in δ¹⁸O also occurs at about 1.8 Ma, suggesting that the source area and vapor transport pathway changed (Figure 9.2) (Cerling et al. 1988). 

Figure 9.2
Isotopic indicators of open, grassy environments from the Koobi Fora Basin and from the South African hominin sites, showing small but variable presence of grasses prior to 1.8 Ma, and a distinctive shift to open habitats after this time. The sequences are as follows: (a) pedogenic carbonate δ¹³C, (b) δ¹⁸O from the Koobi Fora Basin, shown alongside, and (c) calculations for the percentages of browsers and grazers from Makapansgat and Sterkfontein. The arrows provide some guidance about the predicted ranges for pure C₃ and C₄ for (a) and (c), and some pointers to interpretations of the record in (b). Data for (a) and (b) are from Cerling et al. (1988), and they are expressed relative to an age model calculated relative to depth data in the same source. The data for (c) comes from Sponheimer and Lee-Thorp (2003), and Luyt and Lee-Thorp (2003).
et al. 1988). The $\delta^{13}C$ and $\delta^{18}O$ sequences for the Turkana basin shown in Figure 9.2 also illustrate the variability of the results for each period, indicating a rather broad view of vegetation structure. Additional data sets from a wider range of regions and periods have been completed (Kingston et al. 1994; Sikes et al. 1999; WoldeGabriel et al. 2000). These data show a rather complex and variable overall mix of wooded terrain that tends to deemphasize the contributions of C$_4$ grass to the overall mix.

Isotopic studies of fossil faunas, on the other hand, can be designed to investigate the various components of ancient flora. A number of isotopic data sets are now available for Pliocene and Pleistocene faunas that demonstrate presence or absence of C$_4$ grasses in East and South Africa, (Morgan et al. 1994; Cerling et al. 1997; Sponheimer and Lee-Thorp 1999; Lee-Thorp et al. 2000; van der Merwe et al. 2003), and in Chad (Zazzo et al. 2000). In the Chad case, the faunal isotopic data demonstrated significant grassy vegetation from the Late Miocene through the Pliocene (Zazzo et al. 2000). In East Africa, faunal isotope data have in some cases run counter to the perspective afforded by pedogenic studies. At Olduvai, for instance, the isotope data from fauna suggest a greater C$_4$ biomass (van der Merwe et al. 1999) than suggested by the soil carbonates. Another contradiction occurs in the Awash of Ethiopia, where de Heinzelin et al. (1999) suggest a wooded environment at $\approx$2.5 Ma based on presence of certain key fauna (Colobus and Tragelaphus) and soil isotope values, but faunal isotope analyses suggest a significant proportion of C$_4$ grazers (Levin et al. 2004). These discordances suggest that different parts of the ecosystem are being sampled. The advantage of faunal isotope data is that they are abundant in the actual sites associated with hominin activity, and because we can follow first principles to establish abundance of C$_4$ without assumptions about dietary preferences.

No pedogenic carbonate isotope record exists for the regions associated with the South African hominin sites, and the sites are not as old as many in East Africa. The nature of the karstic infill sites present serious challenges for determining the nature of long-term vegetation change. Faunal $\delta^{13}C$ data from all the more important sites analyzed to date (Makapansgat, Sterkfontein, Swartkrans, Kromdraai) have shown that C$_4$ grasses were present from the earliest periods associated with hominins, about 4 Ma or earlier, onward (Lee-Thorp and van der Merwe 1987; Sponheimer et al. 1999; van der Merwe et al. 2003; Hopley et al. 2006). On their own, these data demonstrate presence of C$_4$ but are not very informative about changes in proportions of woody or grassy cover. A “C$_3$/C$_4$ index” has been developed, which is essentially an isotopic expression of the “alcelaphine + antilopine” index developed by Vrba (1980); it is based on the proportions of genera (Sponheimer and Lee-Thorp 2003), or individual specimens (Luyt and Lee-Thorp 2003), falling into one of the grazer, mixed feeder or
browser categories as determined by $\delta^{13}C$. The underlying idea is that browsers will be favored in a closed habitat with many trees, while grazers will be favored in open, grassy landscapes (Sponheimer and Lee-Thorp 2003). When applied to a series of sites to construct a sequential view, the results suggest that the most significant shift toward open, grassy landscapes occurred about 1.6–1.8 Ma (Figure 9.2) rather than at $\sim$2.4–2.6 Ma.

Isotopic data from the Buffalo Cave speleothem, in the Makapansgat Valley, provides more detailed information about vegetation change in this important time period. The speleothem is dated by independent means to between 2 and 1.5 Ma (Hopley 2004). The detailed $\delta^{13}C$ sequence shows cyclical fluctuations in the proportions of C$_4$ grass, with a dominant variability at $\sim$40 Ka, indicating that the major control is the angle of the Earth as it orbits the Sun, and known as the obliquity cycle. Precessional cycles clustered around 20 Ka, due to the Earth’s “wobble”, are also visible. This sequence shows a $\sim$1.7 Ma shift to higher proportions of C$_4$ as before, but importantly, that this was but part of a cyclical pattern. The entire speleothem shows a slight long-term trend toward grassier conditions. Variability in the $\delta^{18}O$ (reflecting rainfall) seems to be most strongly controlled by precessional cycles, in good agreement with those shown for the Tswaing Crater Lake Late Pleistocene sequence (Partridge et al. 1997), and for some Pliocene East African lakes (Trauth et al. 2005). Other stalagmite isotope data from Botswana (Holmgren et al. 1995) and Cold Air Cave in the Makapansgat Valley (Holmgren et al. 2003; Lee-Thorp 2004) hint at considerable floral and rainfall fluctuations but these records are too intermittent or too short to demonstrate precessional cycles. Although both $\delta^{13}C$ (reflecting vegetation) and $\delta^{18}O$ (reflecting rainfall) in the Buffalo cave speleothem are orbitally controlled, the differences in dominant orbital forcing modes between them emphasize the complexities of climate and environment, and the need for multiple sources of evidence.

The shift to grassier conditions in South Africa about 1.6–1.8 Ma is entirely concordant with the shift to open ecosystems in East Africa at the same time. This might be one occasion in which environmental shifts are in phase in East and South Africa.

These changes in floral composition, which can be documented using isotopic tools, are important for evaluating competing hypotheses about links between environment and hominin evolution. What does the floral information tell us? For one, the broad correspondence between the emergence (first appearance) of C$_4$ grasses and hominin bipedalism still holds, in spite of observations that locally, environments may have remained relatively closed. The underlying connection might be dietary rather than locomotor. $\delta^{13}C$ data on hominin diets have, almost without exception, shown an involvement with C$_4$-derived foods.
The implication is that early hominins chose to make use of these new food sources, even if C₄ grass remained a relatively minor component of the ecosystem. We need to test how far back in time this dietary flexibility goes.

There is widespread agreement on the appearance of more open, grassy habitats around 1.6–1.8 Ma. Given the increasing evidence for presence of a fully bipedal hominin equipped with more sophisticated stone tools (including hand-axes) from about this time, it is tempting to draw links between these two occurrences. In this case, we can suggest with some confidence that there is a real environmental “shift,” but the exact nature of linkages to hominin behavioral and evolutionary shifts still require further investigation. Finally, the evidence for cyclical floral and moisture changes from the speleothem data, if upheld, requires reappraisal of several interpretations we have made. These have to do with the issue of time-scale and the nature of the fossil record. Most of the existing data rely on material that can, in principle, reflect small time-windows but the chronologies with which we have to work are quite gross. As a result, what emerges is rather a lot of noise and only the really large-scale environmental trends. The speleothem data also forcibly raise the issues of variability and cyclicity, which are crucial to the “variability selection” hypothesis advanced by Potts (1996, 1998).

### 9.2.5 Aridity indices from oxygen isotopes

Africa never experienced the large temperature swings associated with glacial to interglacial shifts at higher latitudes, and the climate variable of most importance and influence seems to have been rainfall. An overall trend toward aridification has been inferred from the visible trends toward more open, grassier African landscapes over the last ~5–6 Ma, as discussed earlier. However, although aridity and forest diminishment may well be linked in certain respects (for example, maintenance of equatorial forests requires high rainfall), the two are not necessarily tightly connected in savanna habitats. In their report on the isotopic data from pedogenic carbonates from Turkana from ~4 Ma, Cerling et al. (1988) note that the presence of these carbonates through the sequence is indicative that arid conditions were present from the lower sections. Since the δ¹³C data of pedogenic carbonates and fauna in the region shows that the proportions of C₄ grasses remained fairly modest for millions of years after their first appearance, these data suggest strongly that tree density/open landscapes and aridity should be delinked. Studies of modern savanna ecosystems show that lower rainfall often favors more thicket and bushland rather than grass (Scholes and Walker 1993; Owen-Smith 1999). It remains important to establish
independent indicators for aridity. A number of isotopic approaches have been, or are, in the process of development.

As illustrated in Figure 9.2, the Turkana Basin pedogenic carbonate $\delta^{18}O$ sequence suggests that a change in East African rainfall patterning occurred around 1.8 Ma. Since $\delta^{18}O$ values prior to this time were more negative, and those thereafter more positive, the suggestion is that the dominant moisture source changed from a distant (perhaps the Atlantic Ocean) to a closer source, likely the Indian Ocean. The $\delta^{18}O$ values in the latter period are sufficiently enriched to suggest that processes of evaporation also exerted an influence (Figure 9.2). This kind of information, therefore, provides some hints about development of aridity, but little detail.

Isotopic ratios from ostrich or ratite eggshells show great promise as aridity indicators, where the potential is to extract subtle and quantifiable indications of moisture shifts in the past. Johnson et al. (1997) used dual $\delta^{15}N$ and $\delta^{18}O$ data from ostrich eggshell in the Equus Cave hyena accumulation to document moisture fluctuations associated with Late Glacial to Holocene climate shifts. However, no similar studies have been undertaken for earlier periods of interest for hominin evolution, possibly because of the difficulties associated with the organic fraction in older material. Fortunately, data from modern and Late Pleistocene–Holocene archeological sites show that $\delta^{18}O$ alone provides a reasonable aridity index (Lee-Thorp and Talma 2000; Ségalen 2003). $\delta^{18}O$ from the eggshells of earlier ratites has been used to show continuously high, but fluctuating aridity in the Namib from the Miocene to the Present (Ségalen 2003; Ségalen et al. 2006). The main constraint is the chronology, which of necessity is based on biostratigraphy and thus provides only rather crude time intervals. A related tool based on fossil tooth enamel is under development (Schoeninger et al. 2003; Levin et al. 2006), which employs $\delta^{18}O$ differences between animals that use environmental water, and those that rely on plant water and in turn reflect the influences of relative humidity (and aridity). Both of these tools hold potential but have not yet yielded information of direct consequence for addressing questions about climate trends and hominin evolution.

9.3 Conclusions

We have attempted to place some of the long-standing questions about the possible linkages between hominin evolution and environmental changes in an isotopic context and on a sound footing. There are a number of principles and constraints that must be considered for these applications or the results will be of limited value. In doing so, we may have rather overemphasized the problems and
constraints. So, in our concluding remarks, we would like to emphasize some of the solid advances that have been made over the last couple of decades.

A great strength of isotopic approaches to paleoenvironments clearly lies in the area of delineating floral changes, most particularly the presence and proportions of C₄ grasses in the plant biomass. There are a couple of relatively minor disagreements evident from some of the pedogenic versus faunal approaches, but in general, a clear picture emerges. C₄ grasses emerged about 6–8 Ma, probably earlier at the lower latitudes (Cerling et al. 1997), and they remained a visible, but modest and fluctuating, component of the vegetation for several millions of years. Sometime around 1.8 Ma, grasslands took off to become really major components of many African ecosystems, and this change occurred in both East and southern Africa. It is at this point that we probably best see the birth of a modern “world” complete with the vegetation and faunal distributions that we associate with todays “typical” African environments. At the same time, new evidence points to the cyclical nature of environmental change for both flora and rainfall, which is strongly related to orbital forcing cycles of obliquity and precession. These cycles appear to have some considerable time depth. Isotopic evidence for aridity and possible aridification trends is at present thin, but the tools for developing these lines of evidence are now available.

What can these trends, shifts, and cycles tell us about hominin adaptations and evolutionary pathways? Are these issues linked, and if so, how? As noted earlier, the Savanna hypothesis fell from popularity sometime ago because the emergence of bipedalism was pushed back in time beyond estimations for the emergence of savannas, and because immediate environments associated with many early hominin sites suggested closed rather than open conditions. δ¹³C data suggest, however, that the hypothesis might still hold some substance albeit in a rather different sense. For one, the emergence of C₄ grasses and bipedalism is still broadly concordant. The δ¹³C data show that these grasses remained relatively modest components of the biomass for a very long time after their first emergence. But the biomass associated with these grasses may have quickly become important to hominins. Without exception, all δ¹³C studies of hominin diets have shown that significant proportions of their diets contained C₄-derived carbon (Lee-Thorp et al. 2003) (see Sponheimer and Lee-Thorp Vol. 1, Chapter 17). The implication is that when grass-related foods became available, hominins chose to make use of these new resources, a development that may be suggested as a defining characteristic of hominins not shared with our closest living relatives (Sponheimer et al. 2005). This hypothesis has yet to be tested on earlier material. On present evidence, it would seem that a link between hominin emergence and environmental change is still there, but it is not quite as we anticipated it would be.
We can also use the isotopic data to evaluate other hypotheses linking climate or environment and evolution. There seems to be no strong isotopic evidence to support the idea of a large climate-driven shift about 2.4–2.8 Ma, as suggested in the turnover-pulse hypothesis (Vrba 1980). Rather, the evidence from δ13C in fauna and pedogenic carbonates from East and South Africa overwhelmingly suggests that the most significant biomass change to more open, grassy ecosystems occurred near 1.8 Ma. All available evidence suggests that this was indeed a big change. It is tempting but nevertheless speculative to suggest that the rise and success of a habitual, fully bipedal, more technologically advanced hominin, viz. *Homo erectus sensu lato*, is in some way connected with this widespread shift in African environments.

The nature of much of the isotopic evidence produced to date does not permit a detailed test of the variability selection hypothesis (Potts 1996, 1998). This is because we tend to produce data averaged in large time chunks, and the variability is mostly hidden. The new speleothem isotope paleoenvironmental data (Hopley 2004), as well as data emerging from East African lakes (Trauth et al. 2005), represent new departures. The Buffalo Cave δ18O and δ13C data sequence suggests orbital control on rainfall and vegetation, respectively, for ~0.5 Ma in the Pliocene and Pleistocene. That the δ18O data show a dominant precessional cycle very similar to the cycles evident from the Tswaing Crater in the last 180 Ka (Partridge et al. 1997) suggest that it is a persistent feature. The difference in cyclicity between δ18O and δ13C underscores the complexity of climate control on environmental variables, where it can be discerned. Above all, and in agreement with the Saharan dust cycles (deMenocal 1995), the data suggest that the obliquity and precessional orbital cycles remained underlying drivers of environmental variability well before the advent of the very large 100 Ka climate swings after ~0.8 Ma. This kind of sequence may at last provide greater land-based substance for testing Potts (1996, 1998) variability selection hypothesis.

10 Chronometric Methods in Paleoanthropology

 Günther A. Wagner

Abstract

The aim of archeochronometry is the numeric dating, that is in term of years, of archeological and paleoanthropologic events or processes. The methods that are currently applied with most success are all based on the physical phenomenon of radioactivity. Their development underwent in the last few decades—and still undergoes—rapid progress. It is, in particular, the improvement in time resolution but also the application to novel sample materials as well as the extension of the age range of numeric dating that left a strong impact on modern paleoanthropology. This contribution introduces into the principles of radiometric dating. The most frequently applied dating methods, such as the potassium-argon, the uranium series, the fission track, the luminescence, the electron spin resonance, and radiocarbon techniques, are described. Their potential for paleoanthropology is illustrated using various examples covering the period since human entered the scene few million years ago.

10.1 Introduction

In paleoanthropology—as in any historically oriented discipline—time when something happened is the fundamental quantity. Recorded events do not make sense until they are arranged in their correct chronological order. Once such order is known, a mutual, causal relationship between the events may be confirmed or rejected. For instance, the coexistence of Neanderthals with modern humans excludes any hypothesis of simple evolution of the first into the second. Furthermore, a firm chronological database enables assessing the duration and the rate of processes, as is exemplified in the case of the remarkably fast-spreading of Homo erectus out of Africa. It is exactly for these reasons that the rapid progress, which chronometric dating experienced during the past few decades, inspired substantially the development of modern paleoanthropology.
Chronometry refers to the measurement of past time in terms of years, i.e., it leads to numeric age results. Before the introduction of chronometric dating to prehistory, age determination relied essentially on the principles of stratigraphy, which reveals merely the relative order of the records. The turning point came around 1950 with the development of radiocarbon dating, soon followed by potassium–argon and other dating techniques. By now, there are several chronometric dating methods available, which are based on physical phenomena. Since the result of a physical measurement represents only a more or less accurate approximation of the sought after, true value, which is and remains unknown, the often used term “absolute” dating seems inappropriate and should be avoided. Instead the term “chronometric” or “numeric” dating is recommended. The estimated deviation of the measured age value from the true one is given by the error. The error $\pm \sigma$ describes an interval from $(t - \sigma)$ to $(t + \sigma)$ surrounding the measured age $t$ so that the true value is expected with a certain probability within this confidence interval. Consequently, the error is an integral part of the age result and must not be omitted.

For numerical dating, one needs “clocks,” i.e., natural time-dependent processes that lead to quantifiable changes within prehistoric timescales, whereby the rate of the process needs to be known. Furthermore, the process must be reset—like a stopwatch—at the moment that is of interest to the paleoanthropologist, for example, in case of a stony artifact it is not the age of the stone itself but that of the manufacture which is of major concern. Processes which fulfill these requirements are rare. It was the discovery of radioactivity by Henri Becquerel in 1896 which provided such process. Because radioactive decay is a property of the atomic nucleus, its decay rate is insensitive to ambient parameters, such as temperature, pressure, and chemical bonding, i.e., the radioactive clock runs steadily, regardless of environmental influences. For this unique property, radioactivity may aptly be called the “mother of chronometry.”

A nuclide is an atomic species that is characterized by its numbers of nuclear protons and neutrons. Their sum is the mass number, which is indicated as superscript to the upper left of the element symbol. To give an example, the nuclide $^{14}$C consists of six protons, which define the element carbon, and eight neutrons. Nuclides belonging to the same element are called isotopes, i.e., they have the same number of protons but different mass numbers, such as the three carbon isotopes $^{12}$C, $^{13}$C, and $^{14}$C. Most natural nuclides are stable, but others disintegrate spontaneously—a phenomenon called radioactivity. The rate of this disintegration is nuclide-characteristic. The radioactivity $\frac{dN}{dt}$ (in the unit of becquerel, Bq [s$^{-1}$]) is defined as the fraction $dN$ of the radioactive parent nuclide $N$ (with initial amount $N_0$) that disintegrates within the time interval $dt$ into the radiogenic stable daughter nuclide $D (= N_0 - N)$. 

Chronometric methods in paleoanthropology
\[
\frac{dN}{dt} = -\lambda N = -\frac{\ln 2}{t_{1/2}} \cdot N
\]

(1)

whereby \( \lambda \) \([a^{-1}]\) is the decay constant and \( t_{1/2} \) \([a]\) the half-life \((= 0.693/\lambda)\).

By integration, one obtains the equation

\[
\frac{N}{N_0} = e^{-\lambda t}
\]

(2)

and substituting \((D + N)\) for \(N_0\)

\[
\frac{D}{N} = e^{\lambda t} - 1
\]

(3)

The age \( t \) \([a]\) can be derived, depending whether \(N_0\), \(N\), or \(D\) is known, according to one of the following equations:

\[
t = \frac{1}{\lambda} \ln \left( \frac{D}{N} + 1 \right)
\]

(4)

\[
t = \frac{1}{\lambda} \ln \left( \frac{N_0}{N} \right)
\]

(5)

The use of a radioactive system for age determination presupposes that neither the parent nor the daughter nuclides are lost or gained except through the decay process itself—a condition that is known as closed system.

There are several types of radioactive decay: \(\alpha\)-decay takes place under, the emission of an \(\alpha\)-particle, which is a \(^4\)He nucleus. During \(\beta\)-decay, the nucleus emits a \(\beta\)-particle, which is an electron whereby a neutron is converted into a proton. Electron capture occurs when the nucleus captures an extranuclear, orbiting electron from the innermost atomic shell (K-shell) whereby a nuclear proton in converted into a neutron. During spontaneous fission, the atomic nucleus splits into two heavy fragments and two or three neutrons. Some nuclides exhibit a dual decay mechanism, as \(\alpha\)-decay and spontaneous fission for \(^{238}\)U.

Radioactive decay is generally accompanied by the emission of energy discrete \(\gamma\)-rays—a type of electromagnetic radiation coming from the exited nucleus.

Instead of being stable, the daughter nuclide may be radioactive and disintegrate itself. Several such radioactive daughter nuclides following each other form a decay chain until finally a stable end product is reached. Most prominent for chronometric dating is the decay chain starting from \(^{238}\)U and ending at \(^{206}\)Pb involving several steps of \(\alpha\)- or \(\beta\)-disintegration. If the decay chain stays undisturbed, i.e., under closed-system conditions, a balance between production and decay of the interim members is gradually established. At this stage, which is called radioactive or secular equilibrium, all radioactive members \(N_1, N_2, N_3\), etc.
Assume equal radioactivity \( \frac{dN}{dt} \)

\[
\dot{\lambda}_1 N_1 = \dot{\lambda}_2 N_2 = \dot{\lambda}_3 N_3 \quad \text{K, etc.} \quad (6)
\]

In nature, various kinds of radioactive nuclides occur and many of them can be used for chronometry. Due to their origin, these nuclides can be divided into various groups: Primordial nuclides are still left over from the time of nucleosynthesis and, thus, are older than the formation of the earth (e.g., \(^{238}\text{U}\)). Radiogenic nuclides are produced by radioactive decay (e.g., \(^{230}\text{Th}\)). Cosmogenic nuclides are formed by the interaction of cosmic rays with the atmosphere and the earth’s surface (e.g., \(^{14}\text{C}\)). Anthropogenic nuclides are produced in nuclear plants and explosions (e.g., \(^{3}\text{H}\)). For the Quaternary period, there is a wide spectrum of dating methods available (Wagner 1998). Figure 10.1 presents an outline of the radiometric dating methods with sound paleoanthropologic potential.

### 10.2 Potassium–Argon

The K–Ar method covers the whole age range from the beginning of the solar system to the Holocene and has become undoubtedly one of the most important chrono-
metric dating tools since the first attempts were done by Smits and Gentner (1950). The term “potassium–argon” stands for several dating techniques. Apart from the conventional K–Ar technique (\(^{40}\text{Ar}/^{40}\text{K}\)), these are the argon–argon (\(^{40}\text{Ar}/^{39}\text{Ar}\)) and the argon–argon laser techniques. In particular, the latter one plays a crucial role in Plio-Pleistocene chronology whenever volcanic materials are involved. All techniques rest on the same phenomenon—the radioactive decay of the potassium isotope \(^{40}\text{K}\) to the argon isotope \(^{40}\text{Ar}\) so that the amount of accumulated radiogenic argon, in relation to the potassium content, becomes a measure for the age. The various techniques essentially differ in their analytical and gas extraction procedures.

Potassium is the eighth most common element in the earth’s crust and occurs widely in rock-forming minerals such as feldspar and hornblende. One of its three natural isotopes, \(^{40}\text{K}\) with 0.01167% isotopic abundance, is radioactive and disintegrates under electron capture with the decay constant \(\lambda_e\) of \(0.581 \times 10^{-10} \text{ a}^{-1}\) to the stable argon isotope \(^{40}\text{Ar}\). The long half-life of 11930 Ma implies that in the time span of a few million years ago only very low amounts of radiogenic \(^{40}\text{Ar}_{\text{rad}}\) are produced. Therefore, in Quaternary applications potassium-rich minerals, such as sanidine, are preferred. The ultrasensitive analytical technology developed lately allows determining ages as low as few thousand years. The K–Ar clock dates events involving the last complete degassing. In Plio-Pleistocene context, such events are essentially the solidification of volcanic minerals. An important material in this connection are the widespread tephra layers, for which K–Ar dating yields excellent tephrochronologic time marks, in particular, if the tephra are intercalated in early hominid-bearing sedimentary layers.

The K–Ar age \(t\) \(\text{[a]}\) is assessed under the assumptions that, first, no \(^{40}\text{Ar}_{\text{rad}}\) was present in the sample at the moment of the last complete degassing and, second, the subsequently produced \(^{40}\text{Ar}_{\text{rad}}\) remained quantitatively in the sample. Argon is analyzed by mass spectrometry and potassium by atomic absorption. This technique is called conventional K–Ar dating.

Apart from radiogenic \(^{40}\text{Ar}\), there are additional contaminant sources of this isotope. Samples always contain more or less atmospheric argon \(^{40}\text{Ar}_{\text{atm}}\), which must be subtracted from the total \(^{40}\text{Ar}\) in order to obtain the radiogenic fraction \(^{40}\text{Ar}_{\text{rad}}\). This correction is possible owing to the known isotopic abundance of atmospheric argon \((^{40}\text{Ar}/^{36}\text{Ar})_{\text{atm}} = 295.5\), requiring the measurement of the isotope \(^{36}\text{Ar}\) in addition to \(^{40}\text{Ar}\). Argon as a noble gas is chemically inert and thus, should be driven out of the crystal lattice during sufficient heating so that the K–Ar clock is reset. If the degassing is incomplete, the extraneous \(^{40}\text{Ar}\) component is left over, resulting in an overestimate of the K–Ar age. Such nonatmospheric argon contamination needs to be identified and overcome, which is achieved by the single-grain or isochron-dating techniques. The younger
the rock, the less abundant is the radiogenic $^{40}\text{Ar}$ and the larger is the fraction from contaminant argon sources. Therefore for the age determination of Quaternary samples, special K–Ar techniques were developed, which allow analyzing minute proportions of radiogenic argon.

After the resetting event, the K–Ar system must stay closed. Partial loss of argon results in an underestimate of the K–Ar-age value. The leaking of argon from minerals may happen continuously during weathering or episodically during thermal overprint. For unweathered Quaternary volcanites that cooled quickly after eruption to surface temperature and stayed cool afterward, argon loss rarely causes any problem. If present, argon loss can be recognized and corrected by the step heating $^{39}\text{Ar}–^{40}\text{Ar}$ plateau technique.

In the $^{39}\text{Ar}–^{40}\text{Ar}$ technique, potassium is determined through a nuclear reaction instead of chemical analysis. The sample is irradiated with fast neutrons, whereby the argon isotope $^{39}\text{Ar}$ is produced from the main potassium isotope $^{39}\text{K}$. The abundance of the artificial isotope $^{39}\text{Ar}$ is measured together with $^{40}\text{Ar}$ and $^{36}\text{Ar}$. The age is determined against a standard of known age, which is irradiated jointly with the sample to be dated. The fact that instead of explicit quantities only isotope ratios need to be measured improves the accuracy. A further advantage of this technique over the conventional one is the ability to recognize argon loss or extraneous argon. This is achieved by stepwise heating and differential degassing the sample whereby for each step the $^{40}\text{Ar}/^{39}\text{Ar}$ ratio of the released argon is measured. In the absence of argon loss and of excess argon, the corresponding ages display an age plateau.

The laser technique is a variant of the $^{39}\text{Ar}–^{40}\text{Ar}$ technique. The heating is achieved under a laser beam. The sample is either incrementally heated and finally fused—analogous to the plateau technique—or without gradual degassing directly fused and analyzed. The main advantage of this technique is its ability of analyzing single grains in the submilligram range. The grain-discrete probing enables to identify contaminating detrital grain populations by their higher age.

To test whether the K–Ar system is disturbed by excess argon, the isochron technique is also used. It relies on cogenetic fractions from the same rock sample that have different potassium contents. In the isochron diagram, $^{40}\text{Ar}/^{36}\text{Ar}$ is plotted against $^{39}\text{Ar}/^{36}\text{Ar}$. All data points of the subsamples lie on a straight line (isochron) whose slope defines the age and whose intercept with the y-axis reveals the initial $^{40}\text{Ar}/^{36}\text{Ar}$ ratio: if no excess argon is present at the atmospheric ratio of 295.5 and if present at a higher value. Also $^{36}\text{Ar}/^{40}\text{Ar}$ versus $^{39}\text{Ar}/^{40}\text{Ar}$ diagrams are used. In this case, straight lines of negative slope define undisturbed systems. Usually isochron plots are applied in connection with argon–argon laser single-grain analysis. In such case, it is important to probe a sufficiently large number of crystals in order to discriminate between xenocrysts (older crystals incorporated
into the volcanic rock), phenocrysts (crystals that solidified from the volcanic melt before eruption), and the crystals formed during the volcanic eruption (Chen et al. 1996).

Of particular significance are tephra horizons that are intercalated in sedimentary sequences. The ages yield invaluable tephrochronologic and stratigraphic time markers. Our knowledge about the early hominids, their evolution, and dispersion rests essentially on K–Ar data of such tephra. However, tephra layers in sediments may be reworked and thus contaminated with older mineral detritus of various provenances. In such case, bulk K–Ar or Ar–Ar dating of mineral concentrates yields an integrated age that is too old with respect to the event of volcanic eruption. For this reason, but also for the recognition as well as correction of excess argon, single crystal probing is required in order to identify the various components of different age. This is optimally achieved with the grain-discrete Ar–Ar laser technique. Suitable mineral phases are potassium-bearing feldspars, such as sanidine and plagioclase, but also biotite, hornblende, and acidic glass shards.

One of the most renowned sites with early hominid fossils is Olduvai Gorge, Tanzania. The ca. 100 m thick Plio-Pleistocene sediments contain numerous tephra horizons and lava flows. Remains of *Australopithecus boisei* were uncovered as well as stone tools in Bed I. Continuous efforts to date this bed had aroused controversial views on *H. habilis* and its age. Finally, single grain $^{40}$Ar/$^{39}$Ar laser-fusion dating succeeded in establishing a detailed and reliable chronology (Walter et al. 1991). Feldspar grain populations of different ages were observed so that the decisive tuff component could be distinguished from older, reworked contamination. The weighted means of single grains from this juvenile component are $1.798 \pm 0.004$ for Tuff IB and $1.779 \pm 0.007$ Ma for Tuff IF within sedimentary layers that include the fossil hominids. The oldest Oldowan-type stone tools, discovered at Gona, Ethiopia, have an age of 2.6–2.5 Ma. They are associated with cut-marked bones. The dating of the artifact-bearing layer is based on an overlying tuff, which yielded $2.53 \pm 0.15$ Ma as weighted mean of single-plagioclase $^{40}$Ar/$^{39}$Ar ages, and the underlying Gauss-Matuyama paleomagnetic boundary, which is placed at 2.58 Ma (Semaw et al. 2003). One of the first attempts to date basalt flow with K–Ar is that by von Koenigswald et al. (1961) who studied the massive flow underlying Bed I at Olduvai and found an age of $1.3 \pm 0.1$ Ma, which is an underestimate probably due to argon loss. At the Pliocene site Fejej, Ethiopia, with dental remains attributed to *Australopithecus afarensis*, the fossil-bearing sandstone is capped by fine-grained basalt flows. The whole rock samples from two lowest basalt outcrops were analyzed with the laser $^{40}$Ar–$^{39}$Ar incremental heating technique. Both samples showed long age plateaus from which the means of $3.94 \pm 0.05$ and $4.06 \pm 0.07$ Ma, respectively, were
calculated. When combined with paleomagnetic data from the site a minimum age of 4.00–4.18 Ma was assigned to the fossil teeth, making them among the very oldest remains of *A. afarensis* (Kappelman et al. 1996).

As to the question when and how *H. erectus* migrated out of Africa, K–Ar data are of special interest. The earliest fossil trace of this species in Africa occurs in the Koobi Fora region, Kenya, at 1.8 Ma (McDougall 1985). According to K–Ar evidence, *H. erectus* seems to have appeared practically at the same time already in Western Asia. At Dmanisi, Georgia, fluvio-lacustrine sands with several hominid remains assigned to this archaic species are directly under- as well as overlain by volcanic flows and ashes. This stratigraphic situation allows the application of 40Ar–39Ar–age bracketing, resulting in 1.85 ± 0.1 and 1.81 ± 0.05 Ma for the lower and upper volcanic layers, respectively (de Lumley et al. 2002). Based on 40Ar/39Ar laser incremental ages (1.81 ± 0.04 and 1.66 ± 0.04 Ma) on hornblende, separated from pumice of two *Pithecanthropus* sites in Java, Swisher et al. (1994) claimed that *H. erectus* appeared concurrently in Southeast Asia. However, the stratigraphic position of the former hominid finds seems to be above the dated pumice, so that these 40Ar–39Ar ages can be considered merely as a *terminus post quem* for the arrival of the first hominids in Java (Semah et al. 2000).

For the emergence of anatomically modern humans, the recently discovered fossil *Homo sapiens* at Herto, Ethiopia, in fluvial and lacustrine sandstone with Lower and Middle Stone Age technocomplexes are of prime importance (Clark et al. 2003). The upper age limit for this sandstone unit was determined by 40Ar/39Ar incrementally heated multigrain analysis of anorthoclase from embedded pumice, yielding 163 ± 3 and 162 ± 3 ka, respectively, and of embedded obsidian clasts, yielding 160 ± 2 ka. The lower age is constrained by the 40Ar/39Ar laser fusion mean age of 154 ± 7 ka of single grains from the juvenile sanidine-component, separated from a tuff which caps the fossiliferous unit. These data provide fresh evidence for the out-of-Africa model of *H. sapiens*’ origin.

### 10.3 Uranium series

The general term “Uranium series” comprises several closely related dating methods, which are based on the radiometric disequilibrium within the radioactive decay series arising from the two uranium isotopes 238U and 235U (Ivanovich and Harmon 1992). Also the terms decay series, disequilibrium, or uranium–thorium methods of dating are occasionally applied. In paleoanthropology, it is essentially the 230Th/234U method, which is most important for calcareous remains up to about 400 ka old. Of particular interest for 230Th–234U dating
are secondary carbonates of caves and springs and to a lesser degree also fossil teeth and bones. Occasionally also the $^{231}$Pa/$^{235}$U method is applied up to 150 ka.

The uranium isotope $^{238}$U, which constitutes 99.3% of natural uranium, is radioactive and decays over a chain of intermediate radioactive daughter nuclides to the stable lead isotope $^{206}$Pb. In closed systems, equilibrium develops among all radioactive nuclides within the decay chain. In the state of radioactive equilibrium, all radioactive nuclides possess equal activity (Eq. 6). In nature, most minerals and unweathered rocks represent closed systems, in which radioactive equilibrium persists simply as a result of their geologically high ages. If such a system is disturbed it will take sometime, practically five half-lifes, until the daughter nearly returns to equilibrium with its parent nuclide. For the system $^{230}$Th/$^{234}$U, in which $^{234}$U decays by $\alpha$-emission to $^{230}$Th, disequilibrium arises through geochemical fractionation. Uranium is readily dissolved in groundwater from where it is taken up by secondary carbonates as well as dental/bone tissues. Thorium, on the other hand, stays adsorbed to mineral particles and thus is not dissolved in groundwater. Consequently, fresh calcareous deposits incorporate uranium but not thorium, i.e., $(^{230}$Th/$^{234}$U)$_{t=0} = 0$. During the following 400 ka, corresponding roughly to five times the $^{230}$Th half-life of 75.6 ka, the $^{230}$Th/$^{234}$U system gradually builds up to equilibrium. The time-dependent increase of $^{230}$Th/$^{234}$U enables the determination of the time $t$ elapsed since the event of disturbance.

The essential requirements for dating are that the initial abundance of the daughter is, unless known, negligibly small and that after the disturbance the radioactive system remains closed. Complications in $^{230}$Th–$^{234}$U dating have various sources: (1) During the incorporation, $^{234}$U is not necessarily in equilibrium with its radioactive predecessor $^{238}$U, since in groundwater the activity ratio is $^{234}$U/$^{238}$U > 1 so that the $^{234}$U/$^{238}$U ratio must be determined and taken into consideration for age calculation. (2) The requirement that at deposition the sediment is free of $^{230}$Th is frequently not fulfilled since thorium, and consequently also $^{230}$Th, may be present. Negligible $^{230}$Th contamination is indicated by $^{230}$Th/$^{232}$Th > 20. (3) The system may experience a secondary opening as a result the geochemical mobility of the uranium.

Originally, the activity of the Th and U isotopes was analyzed by $\alpha$-spectrometry. The introduction of thermoionization mass spectrometric (TIMS) by Edwards et al. (1986/87), which requires less than 1 g of sample material and provides high age precision, brought a great impetus for $^{230}$Th–$^{234}$U dating. Under favorable circumstances age precision better than 1% can be obtained. The uranium content should be more than 0.1 $\mu$g/g.

When sampling speleothems (calcareous flowstones formed on the cave floor), dense and pure carbonates should be collected in order to minimize the
dangers of open system behavior and $^{230}\text{Th}$ contamination by detrital components. In the Tongtianyan Cave, Guangxi, China, one of the few fossils of *H. sapiens* in China was discovered. Several speleothem layers, intercalated in the cave sediments, were dated by $^{230}\text{Th}/^{234}\text{U}$. The age results of $13.5 \pm 2.3$, $63.1 \pm 2$, and $148 \pm 4$ ka for three layers from top to bottom, respectively, follow the stratigraphic order (Shen et al. 2002). Although the stratigraphic position of the hominid find is to some extent uncertain, it is certainly below the second layer. This renders this finding as one of the earliest in East Asia, indicating that the Moderns arrived there before 63 ka. Depending on the measurement precision, the $^{230}\text{Th}/^{234}\text{U}$ system in speleothems older than 350 ka often shows equilibrium so that only a *terminus ante quem* can be given for the age. This situation was met in the fossil hominid sites known as the Sima de los Huesos, Spain, and the Caune de l’Arago, France. At Sima de los Huesos, the numerous human individuals, which are considered as evolutionary ancestors of the Neanderthal, are overlain by a speleothem that is in equilibrium and thus older than 350 ka (Bischoff et al. 2002). Analogously, the pre-Neanderthals found in the Middle Pleistocene unit III at Caune de l’Arago must be older than 350 ka (Falguères et al. 2004). At the famous Zhoukoudian site near Peking, with the occurrence of *H. erectus*, commonly known as Peking Man, speleothems that are intercalated in the fossiliferous sediments were $^{230}\text{Th}/^{234}\text{U}$-dated. In most samples, the $^{230}\text{Th}/^{234}\text{U}$ system was close to equilibrium. However, high-precision analysis of these nuclides enabled to push the dating method to its upper limits, which is at 500–600 ka age range with the present instrumentation (Shen et al. 2001). The results indicate that the youngest member of *H. erectus* at this site is >400 ka and the oldest members from the lower layers significantly older than 500 ka.

The $^{230}\text{Th}/^{232}\text{Th}–^{234}\text{U}/^{232}\text{Th}$-isochron technique permits determining the initial $^{230}\text{Th}/^{232}\text{Th}$ ratio. Schwarcz (1989) used this technique for the dating of the sinter crust on the cranium of the classic Neanderthal at Monte Circeo, central Italy. The encrustation on the cranium consisted of a brighter inner and a dark-brown outer layer. The outer layer provided 16 ka. From the inner layer, containing detrital contamination, several subsamples of different U/Th ratio were obtained through fractionated leaching. The slope of the straight line (isochron) through the data points in the $^{230}\text{Th}/^{232}\text{Th}–^{234}\text{U}/^{232}\text{Th}$ diagram gives an age of $51 \pm 3$ ka.

Precise $^{230}\text{Th}–^{234}\text{U}$ dating of travertine, a calcareous spring-sinter, is hampered by the common detrital $^{230}\text{Th}$ contamination and by open system behavior. Applying a microsampling technique, in which 100 mg were selectively drilled from the micrite/spar phases, Mallick and Frank (2002) dated successfully travertine from various Thuringian sites, among them Weimar–Ehringsdorf with pre-
Neanderthal remnants. The results assign these finds firmly to oxygen isotope stage 9.

Buried teeth absorb uranium from the groundwater. The knowledge of the time–function of the uranium uptake is crucial for the $^{230}\text{Th}/^{234}\text{U}$-age evaluation. Since the exact temporal development of uptake is unknown, one has to rely on models such as early uptake (EU) or linear uptake (LU) (cf. ESR). For instance, in order to strengthen dating of the long coexistence of early Moderns and Neanderthals in the Levantine corridor (cf. luminescence), McDermott et al. (1993) applied mass spectrometric $^{230}\text{Th}–^{234}\text{U}$ dating to mammal teeth from the Middle Pleistocene sites Tabûn, Qafzeh and Skhûl, Israel. They showed that at Tabûn, both types of humans were approximately coeval some $100 \pm 5\text{ ka}$. The analyses were carried out on 50–100 mg subsamples of dentine and enamel of the same tooth, whereby it is important that the ages agree to each other, although both subsamples differ strongly in U content and in porosity, indicating EU and closed-system behavior. The mode of uranium uptake can be constrained when $^{230}\text{Th} / ^{234}\text{U}$ is combined with ESR-dating (Grün et al. 1988), which in the meantime became the common practice. Falguères et al. (1997) reported coupled $^{230}\text{Th} / ^{234}\text{U}$ and ESR-dating on horse teeth from Acheulian and Mousterian levels at Micoque, France. The $^{230}\text{Th} / ^{234}\text{U}$ ages of enamel and dentine range widely from 150 to $>350\text{ ka}$. However, when combined with ESR-dating, consistent ages between 300 and 350 were obtained.

10.4 Fission track

Although fission tracks (FT) are not applied as commonly as the other radiometric dating methods in paleoanthropology, they made significant contributions at some important sites in volcanic regions. They are formed by the spontaneous nuclear fission of uranium. Natural uranium consists of the isotopes $^{238}\text{U}$ (99.3%) and $^{235}\text{U}$ (0.7%), whereby $^{238}\text{U}$ decays by spontaneous fission. The decay rate of this fission is $10^6$ times less than that of the $\alpha$-decay of the same isotope. During fission, the uranium nucleus splits up into two fragments. Due to their kinetic energy, both fission fragments are expelled in opposite directions and leave along their path a zone of radiation damage. Both branches together form a straight fission track of $10–20\text{ \mu m}$ in length and several $10^{-3}\text{ \mu m}$ in diameter. By chemical etching, the fission tracks can be made visible under the optical microscope. In the course of time, the tracks accumulate in the minerals. When all tracks are preserved, their number gives the age of the sample. Since the track number depends also on the uranium content, the latter one needs to be known. For U analysis, the thermal-neutron induced fission of $^{235}\text{U}$ is exploited.
The number of the induced $^{235}$U fission tracks is proportional to the U content. Thus, the procedure of fission-track dating essentially involves the counting of spontaneous $^{238}$U fission tracks before and induced $^{235}$U fission tracks after a neutron irradiation.

The principles and application of fission-track dating were described in detail by Wagner and Van den haute (1992). With fission tracks, one dates either the formation or a secondary heating event at which all previous tracks were erased, i.e., the clock was reset. The fission-track method is applicable to ages of $>10$ ka. This requires, however, sufficiently high uranium contents above 100 $\mu$g/g. Zircon, due to its high uranium content, is most frequently used in the paleoanthropologic age range. This mineral may occur in volcanic rocks. Of particular interest are volcanic ashes that are intercalated in sedimentary sequences containing hominid remains and Paleolithic implements. Also volcanic glass, such as obsidian and pumice, is frequently used for fission-track dating.

A commonly met problem in fission-track dating is track annealing. Latent fission tracks gradually fade over time. The fading is accelerated at elevated temperatures, a process known as annealing. Since annealing reduces the apparent fission-track age, it is of fundamental importance. Fading can be recognized by track-length measurements since annealing shortens the tracks. Fortunately, tracks in zircon are rather stable and do not show any signs of fading over several million years at ambient temperatures, although tracks in natural glasses certainly may fade under such conditions.

For fission-track dating of tephra, mainly zircon grains and, to a lesser degree, also glass shards and apatite as well as titanite grains are used. When relying on heavy minerals, the problem of different provenance of the various grains needs to be taken into consideration, a difficulty already discussed (cf. K–Ar dating). Primary volcanic grains in presence of detrital ones can be identified—apart from mineralogical criteria—by single-grain fission-track data. A good case study is that on the Plio-Pleistocene sedimentary sequence of the Koobi Fora formation, Kenya. It contains several tuff horizons, which primarily consist of glass fragments and pumice cobbles and show signs of redeposition. Of particular interest is the KBS Tuff, which is intercalated in hominid-bearing layers. K–Ar data on the KBS Tuff raised in the 1970s a controversy between supporters of a long chronology ($2.61 \pm 0.26$ Ma) (Fitch and Miller 1970) and those of a short chronology ($1.82 \pm 0.04$ Ma) (Curtis et al. 1975). FT dating on zircon ($2.44 \pm 0.08$ Ma) (Hurford et al. 1976) at first seemed to support the high K–Ar age. A later FT study of zircon from the pumice yielded $1.87 \pm 0.04$ Ma (Gleadow 1980) in accordance with the low chronology. Besides methodological aspects, the main reasons for the previous fission-track overestimate of the KBS Tuff are detrital, old zircon grains. A far-reaching study on tuffaceous zircon was
reported by Morwood et al. (1998). At the site Mata Menge, Flores, Indonesia, a layer with stone tools is intercalated in tuffaceous layers. FT dating on zircon from the lower and the upper layer yielded \(880 \pm 70\) and \(800 \pm 70\) ka, respectively. Provided that these grains are primary and not reworked, these findings imply that at that time \(H. \text{ erectus}\) had already reached the island of Flores from Southeast Asia—a journey that requires an amazing sea-crossing capability, even at periods of lowest sea level.

Ashes at prehistoric fireplaces may contain sufficiently heated grains of apatite, zircon, and titanite. Such case was encountered at Zhoukoudian near Peking, with its numerous remains of \(H. \text{ erectus}\), the Peking man. From ashes of the layers 10 and 4, several hundred grains of titanite in the size range of 50–300 \(\mu\)m were separated. As criterion for discriminating completely from partially annealed titanite grains, the length of the fission tracks was utilized. Altogether, 100 grains showed complete resetting and gave mean ages of \(462 \pm 45\) ka for layer 10 and \(306 \pm 56\) ka for layer 4 (Guo et al. 1991), being significantly less than the already mentioned uranium series ages for this site (Shen et al. 2001).

### 10.5 Luminescence

Since its introduction by Daniels et al. (1953) luminescence dating has gradually developed into a powerful chronometric technique, particularly for quartz- and feldspar-bearing materials (Aitken 1985, 1998). In the meantime, luminescence dating has significantly contributed to paleoanthropology. As to the techniques of luminescence dating, one distinguishes between thermoluminescence (TL) and optically stimulated luminescence (OSL). For the latter, the term “optical dating” is also used. Luminescence dating covers a wide age range between 10 and \(10^5\) years and thus is able to reach well beyond the limits of radiocarbon dating. Datable materials comprise various inorganic sediments, such as sand and loess, heated stones, and bleached stone surfaces.

Luminescence dating is based on the time-dependent deposition of energy in the crystal lattice of minerals. This energy stems from ionizing radiation, which originates from natural radioactivity as well as cosmic radiation and is omnipresent in nature. When this radiation, consisting of energetic \(\alpha\) and \(\beta\)-particles as well as photons (\(\gamma\)-rays), interacts with the atoms of a mineral, it transfers energy to them so that electrons can be removed from their original valence-band position in the atom shell. Freed electrons diffuse for a short distance through the crystal lattice and some of them become trapped at lattice imperfections. Trapped electrons are at higher energy levels than those in the valence band. With time \(t\), the electron traps are increasingly filled—the process, which forms the
basis of the luminescence clock. When the crystal is stimulated by heat or light, the electrons are released from their traps, enabling them to recombine with opposite charge carriers whereby the formerly trapped energy is set free. Some of this energy appears as emission of visible light, the luminescence. Depending on the kind of stimulation, one differentiates thermally (TL) from optically stimulated luminescence (OSL). OSL is further split up according to the type of stimulating light such as GR-OSL by green or IR-OSL by infrared stimulation. The intensity of the luminescence signal is related to the accumulated energy dose AD (in unit of Gray, Gy) and, thus, to the time interval ("age" $t$) during which the mineral has been exposed to ionizing radiation. The luminescence age is calculated from AD and the dose rate DR (dose per time, in unit of Gya$^{-1}$).

$$t = \frac{AD}{DR}$$ (7)

From the above equation, it becomes clear that the dating procedure consists of two steps: the determination of AD and DR.

The growth of the luminescence signal with radiation dose starts linearly. However, with increasing dose the number of empty traps that are still available becomes fewer so that the growth curve assumes the shape of exponential saturation. In most cases, saturation is reached after doses of few $10^2$ Gy. This behavior restricts luminescence dating to the last few $10^5$ years. In order to convert the luminescence signal into a dose value, one has to know the sensitivity $S$ (luminescence signal per dose, i.e., the slope of the growth curve). It varies from sample to sample. For a given sample, it is the same for $\beta$- and $\gamma$-radiation but different for $\alpha$-radiation. The sensitivity ratio $S_\alpha/S_\beta$, the so-called $a$-value, needs to be determined but is mostly around 0.1.

Another behavior that limits the age range is fading of the latent luminescence signal in the course of time, i.e., the prerequisite that all centers involved in the signal generation are stable over the complete age range in question. Like any other type of radiation damage, latent luminescence signals are subjected to fading whose kinetics is essentially thermally controlled. As far as near-surface materials at normal ambient temperatures are concerned, natural fading limits the datable age range up to a few $10^5$ years.

An important concept in dating is the resetting of the system: the luminescence systems need to have been reset at the event that is of interest. Complete or at least partial resetting of the latent luminescence signals is caused by exposure to heat or light. Consequently, the last occurrence of such events can be dated, for example, the deposition of sediments or the heating of flint artifacts.

The past few years have seen a lot of progress in the laboratory protocols. Previously it has been the common practice to prepare multiple subsamples (aliquots) and apply various doses in addition to their natural one in order to
evaluate AD. Lately, the so-called SAR-protocol (single aliquot regeneration) is increasingly preferred which regenerates the luminescence signal after artificial resetting (Murray and Wintle 2000). When using regenerated growth curves, AD is evaluated through the value of the artificial dose that exactly matches the intensity of the natural one. In order to correct for sensitivity changes due to the laboratory procedure, a test dose is applied to the aliquot. The advantages of the SAR protocol over the conventional multiple aliquot technique are smaller sample size, less time for sample preparation, and improved analytical precision due to replicate AD determination. The present technology is directed toward single-grain protocols which allow making sure that all grains of a sample show the same luminescence age, which bears a great potential for novel applications (Roberts et al. 1997; Greilich et al. 2002; Jacobs et al. 2003).

Apart from the dose AD, the natural dose rate DR needs to be determined for the age calculation. The ionizing radiation at the earth’s surface originates predominantly from the radionuclides $^{232}$Th, $^{235}$U, $^{238}$U, and their daughter products as well as $^{40}$K and $^{87}$Rb and to a minor extent from cosmic rays. These nuclides emit $\alpha$, $\beta$, and $\gamma$-radiation, each of which has a different penetration depth, which amounts in rocks to ca. 20 $\mu$m, 1 mm, and 30 cm, respectively. One needs to take into account the internal component originating within the luminescence sample as well as the external one from the immediate surroundings. The age determination requires materials of a uniform and defined dose rate. For this reason, one separates the sample into certain sizes, usually the fine grain (4–10 $\mu$m) or coarse grain (100–200 $\mu$m) fractions. Since any water residing in the pore volume of the sample attenuates the dose rate, the moisture content and its possible temporal variation in the sample as well as its environment need to be known. Also the on-site intensity of the cosmic rays has to be assessed. It increases with topographic altitude and decreases with depth below the surface. Temporal variation of the dose rate may be caused also by changing contents of radionuclides due to disequilibrium within the decay chains. All these complications must be considered carefully since they may cause major uncertainties in luminescence dating. For dose-rate evaluation, several techniques are available, which include $\alpha$- and $\beta$-counting, $\gamma$-spectrometry, atomic absorption, and neutron activation analyses.

Luminescence dating of clastic sediments enables to determine when they were formed provided all of the sedimentary grains were sufficiently exposed to daylight before and during deposition. In this way also paleoanthropologic remains can be dated that are embedded in such sediment series. In Central Europe—as well as in other periglacial areas—numerous loess profiles with Paleolithic finds have been TL-dated (Zöller et al. 1991). Also many sands have been dated by OSL. An example is the dune sands of the Acheulian open-air site
of Holon/Israel where alkali feldspar and quartz fractions were dated by OSL as well as TL (Porat et al. 1999). However, the presumption that all grains had been completely bleached at deposition is not necessarily fulfilled. In particular fluvial sands, whose grains were transported under water cover, may contain partially bleached or even unbleached grains. In this case, the apparent luminescence age would be an overestimate. Also postdepositional vertical mixing between sedimentary layers, such as bioturbation, leads to erroneous ages. Luminescence dating of individual grains is able to identify these disturbances. This potential was convincingly demonstrated in the case of the Jinmium rock shelter in northern Australia. Fullagar et al. (1996) reported for the artifact-bearing floor-deposit TL ages of 176 ± 16 and 116 ± 12 ka, predating the first arrival of humans in Australia by more than 100 ka. The data were determined on multiple grain aliquots of quartz. Most scholars received these ages with skepticism and as a possible cause for the too high age, contamination with insufficiently bleached grains was assumed. An intensive OSL-dating program on the same deposits by Roberts et al. (1999), using the single-grain approach, yielded ages less than 10 ka when considering only those grains which had been fully bleached before burial. Single-grain OSL ages of quartz from Malakunanja II date the early human occupation of this Australian site to 55.5 ± 8.2 ka (Roberts et al. 1998).

**Burned flint** is well-suited for TL dating. Due to a relatively low internal dose rate and good TL stability behavior, its datable age range reaches back to about 500 ka and thus covers all phases of the Paleolithic. Clearly, TL dating of flint requires prehistoric annealing (>450°C) of the TL signal, which, fortunately, has been the case for a considerable number of flint artifacts. It is advisable to collect several flint samples from each layer to be dated. Intensive TL-dating studies were carried out at several Levantine sites with rich Lower to Middle Paleolithic lithic industries and human remains of Neanderthals as well as early Moderns. From the site of Tabûn/Israel, Mercier and Valladas (2003) reported stratigraphically consistent TL ages between 302 ± 27 and 165 ± 16 ka, indicating that the technological transition from the Acheulian to the Mousterian occurred some 250 ka ago. At the nearby site of Kebara, a skeleton of a Neanderthal and at the sites of Qafzeh and Skhûl remains of a Proto-Cro-Magnon, a predecessor of modern human, had been unearthed. TL dating on 20 flint fragments from the hominid-containing layer in Qafzeh yielded 92 ± 5 ka. At Kebara, 30 flint artifacts from several layers provided TL ages from 50 to 70 ka, and the layer with skeleton of the Neanderthal gave 60 ka. At Skhûl six burnt flints from the level with the remains of a Proto-Cro-Magnon yielded a TL age of 119 ± 18 ka (Mercier et al. 1993). These data reveal that early forms of modern human existed significantly earlier and synchronously with Neanderthals. At the early Upper Paleolithic site of Geissenklösterle/Germany, seven flint artifacts from the Proto-Aurignacian and
two from the Aurignacian levels ultimately satisfied the criteria of being sufficiently heated (Richter et al. 2000). The samples from the Proto-Aurignacian layer gave a weighted mean of 40.2 ± 1.5 ka. The mean TL age of the overlying Aurignacian level is 37.0 ± 1.4 ka. Altogether these data imply a much earlier beginning of the Upper Paleolithic in central Europe than anywhere in western and southwestern Europe.

A novel development is the OSL dating of stone surfaces that in the past have been exposed to daylight, with resetting of the OSL signal, and have been shielded from light since then. In such case, the moment of the last exposure to daylight is determined. This approach opens—at least in principle—a large potential for archeologic, paleoanthropologic, and geomorphologic applications such as the dating of stone structures and buried lithic implements as well as deposited boulders. Hitherto, the new method has been corroborated for granitoid rocks and successfully applied, in particular to the famous Nasca geoglyphs in southern Peru (Greilich et al. 2005).

### 10.6 Electron spin resonance

Electron spin resonance (ESR) dating is also based on the accumulation of radiation-induced energy in minerals and thus has close links to luminescence dating. Although first attempts to exploit the ESR phenomenon for dating go back to the 1960s (Zeller et al. 1967), as a dating method it did not flourish before the 1980s and is still being developed. The ESR method permits age determination up to few million years, far beyond the range of the luminescence methods, and covers the whole Quaternary period. The most important material for paleoanthropologic ESR application is tooth enamel, but quartz-separates from sediments at prehistoric sites also have a certain potential (Rink 1997). With ESR, one dates either the burial, as in the case of fossil teeth, or the resetting of a previous system as a result of bleaching, as in the case of sedimentary quartz grains or heating of stones.

The ESR phenomenon is caused by paramagnetic centers in the crystal lattice. Radiation-induced trapped electrons, mentioned already in the context of luminescence dating, form such centers and give rise to characteristic ESR signals. The intensity of the ESR signal is a function of the number of trapped electrons and, therefore, of the accumulated energy dose $AD$ that has been absorbed from the ionizing radiation in the course of time. In order to calculate the ESR age, the value of $AD$, obtained from the ESR measurement, is divided by the dose rate $DR$, in the same manner as already discussed for luminescence (Eq. 7).
The quantity of AD is determined by ESR spectrometry, which exploits the fact that trapped electrons are unpaired. Brought into a variable magnetic field and exposed to a given microwave, unpaired electrons show spin resonance at a specific strength of the magnetic field. The condition at which resonance happens is described by the $g$-value, which is characteristic for the type of the paramagnetic center. The energy necessary for the resonance is absorbed from the microwave so that its intensity reduction is a measure for the concentration of the center. The resulting ESR spectrum shows the specific microwave absorption for various centers with different $g$-values. Owing to measurement–technical reasons, the ESR spectra of the microwave absorption are not directly recorded; instead their first derivation as a function of the field strength is plotted. For the evaluation of AD, known doses are applied additively to the sample and a growth curve is established. ESR has the advantage over luminescence that the concentration of the probed centers is not disturbed by the measurement procedure, thus permitting one to establish the growth curve on the same aliquot. Most samples show exponential saturation functions. At normal ambient temperatures of sediments, most ESR centers are sufficiently stable for applying ESR dating up to few million years. The dose-rate determination follows the same principles as already mentioned for luminescence. For ESR-dating samples of a few grams are sufficient, provided the material is homogeneous, but usually larger sample sizes are preferable as they allow one to separate suitable materials in the laboratory and to conduct microdosimetric measurements.

ESR dating of fossil *tooth enamel* plays an important role for Paleolithic sites, mainly because teeth are commonly preserved. Furthermore, the age range covered by ESR dating reaches beyond those of radiocarbon or luminescence dating so that even the Lower Paleolithic becomes accessible. Mammalian dental issue consists essentially of enamel, dentine, and cementum layers. ESR dating is based on the mineral hydroxyapatite, in particular on its carbonate-containing subspecies dahllite, within the enamel. Dentine and cementum are less dense, contain more organic tissue, and take up uranium more easily than dentin. For these reasons, they are not used for ESR analysis but must be taken into account for microdosimetric reasons. The ESR spectrum of tooth enamel has, at $g = 2.0018$, a suitable signal of good sensitivity and high thermal stability.

The quantity of the dose rate introduces considerable problems into the ESR age evaluation. In teeth, one observes often strongly varying uranium contents on microscopic scale causing steep dose-rate gradients, which is in particular the case for the $\beta$-component since the $\beta$-radiation range (ca. 1 mm) is similar to the thickness of the enamel layers. Teeth gradually take up uranium from the groundwater after burial. *In vivo* they contain less than 1 $\mu$g/g U, but fossil ones up to 1,500 $\mu$g/g. This means that the dose rate increases with time and that the
closed-system condition is not fulfilled. To allow for time dependence of the dose rate, distinct models of uranium uptake are assumed such as the early uptake (EU), the linear uptake (LU), and recent uptake (RU) models. The EU-model results in a lower ESR age compared to the LU model due to a higher dose rate on the average. Both model ages may considerably differ from each other, especially for high uranium contents so that samples low in uranium are preferable. Most published ESR-age data are based on assumed U-uptake models. In order to set constraints to the validity of the model, ESR dating is coupled with uranium series dating (Grüner et al. 1988). The comparison the closed-system ages of $^{234}\text{U}/^{238}\text{U}$ and $^{230}\text{Th}/^{234}\text{U}$ with that of ESR enables to discriminate among the hypothetical models. Combined ESR/uranium series dating has become more and more the routine for tooth enamel dating.

The Early and Middle Paleolithic sites of Tabûn, Kebara, Skhûl, Qafzeh and Hayonim, Israel, with rich lithic and human bone inventories play a fundamental role with respect to the early human out-of-Africa dispersion through the Levantine corridor. In order to establish a firm chronology of this migration, ESR-dating has been repeatedly applied to mammalian tooth enamel from these sites, in addition to uranium series and luminescence. Worth mentioning in this connection are, in particular, two results. First, the combined ESR/uranium series tooth age of $387 \pm 50$ ka confirms a $340 \pm 33$ ka TL age on burnt flint for the Lower Paleolithic Yabrudian lithic industry at Tabûn, whereby the U-uptake appears to be more recent than linear (Rink et al. 2004). Second, the ESR ages on teeth from Middle Paleolithic contexts support the early dating of the anatomically Moderns to $80–120$ ka, with the amazing consequence that in the Levant the Moderns and Neanderthals coexisted for about $60$ ka (Grüner and Stringer 1991).

At the well-known South African site Swartkrans, with its wealth of remains of *Australopithecus robustus*, Curnoe et al. (2001) determined one of the oldest ESR ages so far reported. Coupled ESR/uranium series dating on two human and two bovid teeth yielded $1630 \pm 160$ ka with a possible maximum of $2110 \pm 210$ ka, indicating that ESR dating can provide reasonable results for samples of Late Pleistocene/Early Pleistocene age. Also the Atapuerca Gran Dolina site, Northern Spain, with the earliest humans in Europe, *H. antecessor*, was investigated by combined ESR/uranium series dating. From the bottom of Aurora stratum, where the very early human remains had been recovered, three ungulate teeth gave a mean of $731 \pm 63$ ka, which is in agreement with the paleomagnetic age estimate of $>780$ ka (Falguèrèrs et al. 1999).

ESR also permits the dating of calcareous sinter deposits, which show complex ESR spectra partly attributed to organic radicals. Important Paleolithic cave sites have been dated, among them Caune de l’Arago at Tautavel, southern
France. ESR-dating of calcareous deposits under- and overlying the hominid-bearing bed allowed its bracketing between 242–313 ka as upper and 147 ka as lower age limits, respectively. This result is in good agreement with uranium series data of 315–220 ka (Hennig and Grün 1983). ESR-dating was also tried on travertine, e.g., for the profiles Weimar–Ehringsdorf and Bilzingsleben, central Germany, with important hominid fossils (Schwarcz et al. 1988). The data support Middle Pleistocene ages for this site but probably need some revision using the more advanced approach now available.

ESR may also be applied to quartz grains from clastic sediments provided the grains were exposed to light for about 6 months during sedimentary transportation so that the minimum signal level in Al-centers is reached. However, there are so far only a few examples of successful applications, one being the Early Pleistocene Monte Poggio site, Italy, where more than 4,000 Paleolithic flint artifacts were found in sandy beach deposits. Detrital quartz extracted from different archeological levels provided a mean age of 1065 ± 165 ka, which is in agreement with paleomagnetic data (Falguères 2003).

10.7 Radiocarbon (\(^{14}\)C)

Among the physical dating methods, radiocarbon is the most widely known and most commonly applied one in archeology. Essentially it utilizes organic remains from the last 50 ka. In the context of paleoanthropology, this means that only the periods from the Late Middle Paleolithic onward may be dated, which comprise a relatively short section of human presence on earth. Furthermore, its application in the pre-Holocene time range (>12 ka) is complicated by the fact that reliable calibration procedures for \(^{14}\)C dates are not yet available resulting in low accuracy of the true age. Toward the upper age limit, contamination by modern radiocarbon becomes a dominating problem.

Recent natural carbon consists of three isotopes, these are the two stable isotopes \(^{12}\)C (98.89%) and \(^{13}\)C (1.11%), and in very minor traces the radioactive \(^{14}\)C (\(^{14}\)C/\(^{12}\)C ≈ 10\(^{−12}\)), which decays (\(t_{1/2} = 5,730\) a) under β-emission. It is naturally produced in the stratosphere by interaction of neutrons of the cosmic rays with atmospheric nitrogen atoms according to the reaction \(^{14}\)N(n,p)\(^{14}\)C. The average global \(^{14}\)C production rate is 7.5 kg/a but is subjected to considerable temporal variations. Depending on this rate, an equilibrium value between production and radioactive decay is established. Bound in CO\(_2\), \(^{14}\)C becomes quickly distributed throughout the atmosphere. By photosynthesis, CO\(_2\) enters the plants and via the food chain the biosphere. Through dissolution and gas
exchange it moves into the hydrosphere, from where it gets as CaCO$_3$ into marine or limnic sediments and organisms. As long as these reservoirs participate in the carbon cycle, their $^{14}$C concentration maintains the atmospheric equilibrium value. With death of the organism or with carbonate precipitation, the carbon becomes separated from the cycle so that the $^{14}$C input is interrupted. Thereupon the $^{14}$C/$^{12}$C declines due to radioactive decay. Initially it was assumed by Libby (1952) that the atmospheric $^{14}$C/$^{12}$C was constant so that according to this model the conventional $^{14}$C age is calculated (cf. Eq. 5) from the present $^{14}$C/$^{12}$C and an assumed fixed value for $(^{14}$C/$^{12}$C)$_0$. The conventional $^{14}$C age is linked to the reference year 1950 AD, with the notation “BP” (before present) after the age value.

Conventional $^{14}$C ages are incorrect since the simple model condition of a constant initial $^{14}$C/$^{12}$C is invalid. Tree-ring data, for instance, show that within the past 11 ka the initial $^{14}$C/$^{12}$C decreased by ca. 10%, so that a 10-ka old sample results in a $^{14}$C age being ca. 1 ka too young. In order to obtain accurate ages, the temporal fluctuation of $^{14}$C must be recognized. This is achieved by $^{14}$C dating of samples of independently known age. Apart from possible oscillations of the primary cosmic ray flux, the fluctuations in the atmospheric $^{14}$C/$^{12}$C level are attributed to changes in the $^{14}$C production rate caused by the varying magnetic shielding of the primary cosmic rays; in particular the geomagnetic minimum ca. 40 ka doubled the production rate (Beck et al. 2001). Also the magnetic disturbance, originating from the solar activity, modifies the production rate, although to a lesser degree and on shorter timescales. In this way, high magnetic intensities imply low $^{14}$C production rates and, thus, high apparent $^{14}$C ages. On the other hand, the carbon exchange between different reservoirs, mainly the ocean and the atmosphere, affects the atmospheric $^{14}$C/$^{12}$C level. In periods, when the oceanic circulation slows down, less of the “aged” oceanic CO$_2$ is released into the atmosphere so that atmospheric $^{14}$C/$^{12}$C level increases, leading to apparently younger $^{14}$C ages.

Regardless of their origin, these fluctuations necessitate calibration of the $^{14}$C ages. By calibration, the chronologically irrelevant conventional age is converted into a calendar age. This is achieved by calibration curves in which conventional $^{14}$C ages are plotted versus the true calendar ages. For the Holocene, this is done with high accuracy by dendro-calibration. For the Late Pleistocene, other archives than tree-rings are needed due to the scarcity of trees during glacial climate. Annually varved sediments and shallow-water corals, which can be independently dated with uranium series techniques, were used for this purpose. The results of such efforts were presented as INTCAL98 curve (Stuiver et al. 1998), which reaches back to 24,000 calendar years, and the subsequent IntCal04...
(Reimer et al. 2002). In order to extend the calibration back to 50 ka, several attempts were undertaken, using lake sediments, corals from uplifted marine terraces, submerged speleothems, and deep-sea sediments (cf. Bard et al. 2004). In this early period, the conventional $^{14}$C ages are consistently younger than the true ages by 4–5 ka. A particular complication is posed by the strong $^{14}$C fluctuations that are associated with the magnetic minima during the Laschamp and Mono Lake geomagnetic excursions around 40 and 33 ka, respectively, which actually prevent reliable $^{14}$C dating for that period (Conard and Bolus 2003). In order to distinguish calibrated $^{14}$C ages from conventional ones, they are characterized by the notations “cal BC” (calendar years BC), “cal AD” (calendar years AD) or “cal BP” (calendar years before 1950 AD).

Apart from the temporal fluctuations, there are spatial $^{14}$C nonhomogeneities in the materials and reservoirs participating in the carbon cycle. One distinguishes isotope fractionation and reservoir effects. Photosynthesis, for instance, enriches the light $^{12}$C over the heavy $^{13}$C, and in turn the latter over the even heavier $^{14}$C, so that the carbon in plants is isotopically lighter than in the atmosphere. For most materials, the age corrections that result from isotope fractionation are less than 80 a but may amount up to several hundred years, as in the case of marine limestones and organisms. The reservoir effect deals with the isotopic variation of carbon within the reservoir from which the organisms extract their carbon. Such spatial changes may have various causes. If the carbon stays long—with respect to the $^{14}$C half-life—within the same reservoir, the $^{14}$C concentration declines (“aging” of carbon). A prominent example is the “marine reservoir effect” in the oceans where upwelling regions have apparent $^{14}$C ages around 400 a. Also the admixture of “aged” carbon lowers the $^{14}$C concentration, such as “hard-water effect” in carbonaceous ground and surface waters. Reservoir effects result in an apparent increase of the $^{14}$C age. They are difficult to assess.

As for the other radiometric dating systems, the $^{14}$C system also has to remain closed, i.e., carbon must neither enter nor leave the sample. The $^{14}$C age is lowered by uptake of recent carbon. Common sources of contamination with recent carbon are the presence of rootlets, humic acid infiltration, and bioturbation. The danger of contamination by modern carbon is the greater, the smaller is the authigenic $^{14}$C amount and the older the sample. For this reason, the applicability of $^{14}$C dating at high ages is limited by unavoidable contamination rather than by the instrumental capabilities of $^{14}$C detection. The upper dating limit (maximum age) is reached when the $^{14}$C of an old sample cannot be discriminated with sufficient statistical confidence from the background. The AMS technique has the great potential to lower the instrumental background and
thus to extend the maximum age but effectively is limited by the $^{14}$C background due to contamination.

The amount of sample required for $^{14}$C dating depends on the carbon content, the conditions of preservation, the degree of contamination, and the technique of $^{14}$C detection. For $\beta$-counting, either in gas or liquid scintillation counters, 5–10 g of extracted carbon usually is needed. The AMS technique requires carbon in the milligram range. Note that the quoted amounts refer to carbon and not sample. The required amount of the latter one might be larger by a factor of 10 or so, depending on the carbon content.

**Bones** and [antler](https://en.wikipedia.org/wiki/Antler) are the most frequently used paleoanthropologic sample materials for $^{14}$C dating. As long as their inorganic fraction was used, bones were considered as a problematic material for $^{14}$C dating due to open system behavior. However, their organic substance consisting predominantly of various proteins, generally classed as collagen, is more resistant to exchange. The collagen is chemically extracted as acid-insoluble residue and is then usually subjected to AMS analysis. In an extensive program, Conard and Bolus (2003) dated numerous animal bones, the majority of them with anthropogenic modifications, from several Upper Paleolithic sites in the Swabian Jura, Germany. Among these sites were the famous Vogelherd and Geissenklösterle caves with rich finds of small figurines and flutes made of bone. The conventional $^{14}$C ages indicate that in this area, the Aurignacian spans the period between 40 and 30 ka BP and the Gravettian was well-established not later than 29 ka BP. This chronology—which actually is supported by luminescence dating of burnt flint (Richter et al. 2000)—seems to be significantly higher than those at other European sites with comparable Upper Paleolithic assemblages. However, the true chronostratigraphic position and duration of the Aurignacian cultural group cannot be directly deduced from these data due to the strong global fluctuation of the atmospheric $^{14}$C level around this period. Unfortunately, this “Middle Paleolithic Dating Anomaly” coincides roughly with the period of the Upper/Middle Paleolithic transition and the arrival of modern humans as well as the extinction of the Neanderthals, and thus seriously hampers the chronological solution of the basic questions connected with these culture and population changes (Conard and Bolus 2003). Commonly it is believed that the beginning of the Aurignacian is associated with the arrival of modern humans and among the best evidence appeared to be the presence of modern human skeletal remains within the Aurignacian layers at the Vogelherd cave. $^{14}$C dating of these bones, however, revealed that they are Holocene intrusive burials within the Paleolithic levels, leaving open whether modern humans indeed produced the Aurignacian artifacts (Conard et al. 2004).
Another important dating material is charcoal, as for instance at El Castillo cave, Spain. Charcoal samples were taken from different parts of the lowermost beds containing Aurignacian artifacts. The mean $^{14}$C-AMS age of the three samples amounts to $38.7 \pm 1.9$ ka BP (Valdes and Bischoff 1989).

Limnic sediments form an important archive for the climatic fluctuations of the past and if they contain organic matter $^{14}$C dating can be directly applied, in particular to peat and sapropel. An excellent material for AMS $^{14}$C dating are macrofossils, such as nutlets, fruit scales, and leaves, from the sediments. Such fossils are short-lived and free of the hard-water effect. When dating secondary calcareous sinter, the uptake of a certain fraction of “dead” carbon from geologically old limestone must be taken into account, which lowers the reliability of such dates. When using mollusc shells, the marine or hard-water reservoir effect, depending on the habitat of the molluscs, need to be considered. Paleolithic rock paintings commonly contain organic material, such as charcoal, carbonized plant matter, pigments, plant fibers, blood, fatty acids, and beeswax, which enables $^{14}$C dating. The recently discovered rock paintings at Chauvet-Pont d’Arc, France, gave $^{14}$C ages $\approx 31,000$ a BP, using microsamples of charcoal from the paintings (Clottes et al. 1995), and thus belong the earliest examples of prehistoric rock art so far discovered.

10.8 Conclusions

Dating methods based on radioactive decay are in principle independent clocks, i.e., they solely rely on the measurement of radiometric quantities, on known physical constants and natural isotopic abundances. The potassium–argon, fission track, luminescence, ESR, and uranium series methods are such independent clocks. Radiocarbon, on the other hand, is a dependent clock since it requires calibration by independently derived ages, for instance by dendrochronology or uranium series dating.

Radiometric dating provides the base line for calibrating other dating approaches such as isotope-, climate-, bio-, and magnetostratigraphy as well as astronomical and chemical means. All these latter techniques rely on natural changes with varying rates that are more or less predictable. Only through calibration do these techniques become chronometric tools.

During the last decades, a solid chronology for the time period hominids entered the scene since some 5 Ma ago, has been established through radiometric dating. Present methodologic developments focus primarily on improving the time resolution, which is a prerequisite in order to decipher natural and cultural
processes. Paleoanthropologic knowledge and concepts have greatly benefited from these advances.

11 Geological Background of Early Hominid Sites in Africa

Ottmar Kullmer

Abstract

Hominid remains are rare elements in the fossil record. Probably the small population sizes of early hominids, in combination with preservation constraints, limit the probability of a higher frequency of fossil discoveries. The early evolution of mankind appears to be a Pan-African story, even though the distribution pattern of remains concentrates on eastern and southern Africa. More recent findings from the Chad Basin in central Africa demonstrate that fossil hominid remains are not restricted to the eastern part of Africa. The success of exploration in paleoanthropology depends on the discovery of appropriate sediment layers, mainly lake and river deposits with an upper Miocene through Pleistocene age. Knowledge of the geological framework is of great importance in evaluating the potential for fossil preservation in a certain area. To date, three major types of geological megastructures have yielded almost all fossil remains of early hominids: the East African Rift Valley (EARV), the intracratonic basin of Lake Chad, and the fossil-rich cave deposits in South Africa. Each of these regions provides a unique sedimentary setting bearing fossil-rich layers comprising a specific time-span within the last few million years.

11.1 Introduction

The fossil record of man is scanty and discoveries are rare. It seems that the farther back in time we go, the fewer the fossil remains we can expect (Cooke 1983). There are probably several factors involved in diminishing the hard evidence of our own evolution. When a mammal dies in the open, scavengers will immediately work on the carcass, scatter pieces, and probably destroy bones. The surviving parts may be exposed to the hot sun during the daytime and cooled down at night. Extreme temperature differences between day and night lead to cracking due to loss of water and reduction of organic material in the bone fibers.
Usually this process is accompanied by the activity of microorganisms and maybe also by physical transport in riverbeds or on floodplains during torrential rain falls. All of this modifies the original surface of bone or even breaks elements apart. Most of the time, the history of an animal body ends in its complete destruction, unless the bones are covered and protected, e.g., by rapid burial with sediments (Cooke 1983). Sometimes animals are trapped in cavities, like fissures or pits, and their bones are preserved articulated. But even if we have a favorable environment for rapid covering, most of the time postburial chemical and physical processes are destructive, with some rare exceptions favored by special geological environments.

For this reason, the search for hominid fossils depends at a larger scale on the geological setting because the sedimentary environment is a limiting factor upon chances of finding early hominids. Due to the multifarious influences for destruction, each fossil we collect seems to be a stroke of luck. In Africa, the hunt for the discovery of the origin of mankind concentrates on three major types of geological settings with a great potential for new discoveries. These are graben structures, cave deposits, and intracratonic basins that developed during the last 8 million years (Ma), after the hominids diverged from their last common ancestor with the African great apes. Consequently, the East African Great Rift Valley (EARV), with its widespread outcrops of fossil-rich Miocene to Pleistocene deposits, presents a unique situation for paleoanthropological field research. The Rift provided permanent water sources for our oldest ancestors and a rich fauna. A very similar situation is found in intracratonic basins like the Chad depression, occurring as relatively static systems with large lake transgression and regression cycles, varying in time, and sometimes producing fossiliferous deposits of enormous lateral extension. In contrast, the famous South African cave sites, Makapansgat, Sterkfontein, Swartkrans, and Kromdraai, were formed by extensive freshwater karstification and sedimentation processes and their complex cavities were used as shelters for hominids and probably functioned also as traps and scavenger caves.

Geological and paleoanthropological research at African hominid sites has produced a rich database during the last century. Today the geological background information influences the search for the origin of humankind, and the growing knowledge about geology helps us to understand the processes of fossilization and supports the interpretation of individual situations at fossil localities. And the application of digital geographical information systems (GIS), in combination with high-resolution satellite images, has provided a huge additional database for field investigations. Potential fossil localities, in Rift valleys, intracratonic basins, and karstified limestone, can be localized by satellite image analysis. Nevertheless, extensive surveys by experienced field teams
will continue to be the fundamental basis for the discovery of new fossil hominid remains.

### 11.2 Geological setting

The geological setting at hominid localities is not only an important source of information about environmental settings and changes through time at a specific locality or an area but is also an indicator of the probability of finding fossilized bones and is therefore an essential aspect influencing survey strategies. Moreover, it is an important aspect of the transfer of knowledge relevant to a broad understanding of human evolution as a Pan-African story.

Sedimentary formations with a high potential for fossilization are the required geological setting. These consist of deposits that are products of weathering and transport, erosion, and deposition. Sediments are a mixture of different minerals and organic materials deposited on the earth’s surface, or in caves, in interaction with the atmosphere, hydrosphere, and biosphere. Common examples are clays, silts, sands, gravels, and breccias. Due to subsidence of some hundred meters, up to a few kilometers, deposits are typically transformed into sedimentary rock, like sandstone, claystone, or limestone.

Accumulation areas of sediments are divided into marine and continental depositional space.

Even if some of the fossil sites, like Saldanha or Klasies River Mouth in South Africa, are located closely to the ocean shoreline, the most important hominid fossil sites are located in continental deposits. Potential continental bone accumulation localities are fissures, caves, swamps, tar pits, river channels, flood plains, lagoons, and lakes. Such depositional areas can be described as geomorphological units characterized by climate, size, and shape of a sedimentary basin. Geometry and composition of sediments, and the relationship between units, provides information about the milieu of deposition. Physical, chemical, and biological parameters (Table 11.1) inform us about the depositional environment and climatic conditions. These parameters have to be recorded during fieldwork. The sum of all primary characteristics of a sedimentary unit defines the sedimentary facies (Reineck and Singh 1980). The analysis of the facies permits us to understand the sedimentary factors responsible for the appearance of the deposit and the fossils.

Medium, current, wave intensity and velocity, as well as water depth, are relevant physical factors (Table 11.2); these are the important hydrodynamic conditions for the transport of animal remains. Mineral and groundwater composition, including climate, are understood to be the chemical factors of sedimentation
and fossilization. Fortunately, sediments sometimes contain biological factors, faunal and floral remains, in different stages of preservation. The appearance of animal remains in a sedimentary matrix depends on its so-called taphonomic history. The taphonomy (Efremov 1940) includes the two processes, biostratinomy and diagenesis, that describe the pathway from a carcass to a fossil. Biostratinomy (Weigelt 1927) deals with everything that happens to a carcass after an animal’s death, before the remains are buried. Afterward, the fossilization process, including mineral exchange and compaction, is called diagenesis. The fossilization process reduces information about an animal, but it also tells us a story that contains information about the paleoenvironment. The possibility that parts of a given animal will survive for some million years is relatively low due to taphonomy. Fossils are not randomly distributed. There are only a few spots on earth where we can find mammal remains, and there are even fewer places where we can discover hominid fossils. In most assemblages of large mammals from a single locality, the abundance of hominid specimens is less than 0.5%.

After Reineck and Singh 1980.
Nevertheless, the number of collected fossils has increased rapidly during the last decades. More and more research teams, with sophisticated survey strategies, explore for and investigate new fossil sites. Extensive sedimentologic and taphonomic analysis at known localities leads to a broad understanding of fossil site creation.

Commonly, the geographical distribution of hominid localities is used to interpret the origin of mankind and the migration patterns of early hominids (Coppens 1994). One has to consider, though, that the interpretation of the biogeography of a species or even of an evolutionary lineage, can be heavily biased by the factors mentioned earlier, as well as by others, such as those controlling the burrowing and preservation of animal remains.

White (1988) pointed out that the fossil record in eastern Africa is biased toward a representation of the watered axial basins. Classic hinterland sites lacking permanent water sources, e.g., Laetoli, are rare indeed. But this does not imply that these were minor constituents; they may just have not been discovered yet. The preservation of fossils is heavily dependent on the sedimentological environment. Fluviatile milieus do not necessarily grant a permanent burial; many of the fossil localities in eastern Africa are associated with rivers, and a migrating channel bed can alter even a lake margin or floodplain within a short time period.

Chances of finding an original bone association decrease with the transport distance from the point of origin. When discovered, the bone assemblage is likely to represent different individuals from different localities and different time periods (Hanson 1980). Time averaging, the mixing of noncontemporaneous populations, has to be considered when interpreting the history of bone assemblages. Nevertheless, beside sedimentological factors, the effects of time averaging are also dependent on stable or highly fluctuating populations (Behrensmeyer and Chapman 1993).

### 11.3 East African Rift Valley

If we look at the geographical distribution of early hominids in Africa, we recognize that many of the famous sites are aligned in a chain along eastern Africa from Ethiopia via Kenya and Tanzania, to Malawi in the southeast. Localities like Hadar, Middle Awash, Omo, Lake Turkana, Olduvai, Laetoli, and others have yielded a great number of hominid specimens during the last 50 years. These sites are positioned in a geological megastructure, the EARV (Figure 11.1). The EARV extends about 6,400 km from northeast to southeast.

The suture of the EARV follows a fault zone in the Continental crust. Plate tectonics explains the process of break-apart and rifting. The Nubian and
Somalian plates diverge along the main rift axes and result in a great graben with an average width of 30–40 km. The flanks are uplifted, while subsidence forms the graben floor. Active east–west extension leads to an enlargement of the accumulation space. A sedimentary fault basin develops as soon as the subsidence is great enough that an initial drainage system grows along the main faults. Minor rivers and alluvial fans transport material into the basin from the rift shoulders. A complex erosion–sedimentation interaction system starts in the active rift zone.

**Figure 11.1**
The geological megagraben of the EARV (gray area) with its famous hominid sites, extends over more than 6,400 km from the Gulf of Aden and the Red Sea in the north into the Indian Ocean in the southeast at the height of Madagascar. The main rift splits into eastern and western branches just north of Lake Victoria. A schematic transverse section (below) through the Rift Valley shows that the graben shoulders are composed of a stepped block-system separated by normal faults. The center is lowered due to crustal extension and divergence and uplift of the shoulders.
The expression “rift,” or “rift valley,” can be traced back to the definition of Gregory (1896). Accordingly, a rift valley, like the Malawi Rift, is a parallel-sided down-faulted valley some tens of kilometers in width and at least a few hundred kilometers in length (Ring and Betzler 1995). Several smaller-scaled tectonic structures, like half-grabens, horsts, warped blocks, major faults, transform faults, and pull-apart basins can occur within a rift system.

All these geological structures provide space for accumulation, and erosional processes to bury and unearth skeletal remains.

In the history of a mature rift system, diverse environmental settings can be recorded, representing a wide range of habitats. Rifting may end in a marine transgression phase and the birth of an ocean, when the continental breakup continues and rift floor subsidence extends toward the coast, as we can observe happening in the Red Sea and the Gulf of Aden. In other cases, the rifting dynamics may stop after some active phases.

The EARV is probably one of the most attractive rift systems, reflecting several stages of rift development in its longitudinal extension. It therefore provides an important field of research for understanding crust breakup in a continental setting. Over the last 110 years, extensive research has been focused on the EARV (Gregory 1896; Wegener 1912; Krenkel 1922), making the East African rift system one of the best documented continental rift systems on Earth (Ring and Betzler 1995). Two areas have been of major interest: the Ethiopian Afar Triangle (Baker et al. 1972; Mohr 1987) in the Northeast at the horn of Africa, because of its special rifting situation as a triple junction of three crustal plates; and the Kenyan or Gregory Rift (Baker et al. 1972, 1988; King 1978; Crossley 1979; Strecker et al. 1990), as the eastern branch of the graben system.

Extensive magmatism and volcanism accompanies sedimentation in the graben. The oldest rifting phases are recognized in the northeastern parts at the western boundary of the Sinai Peninsula marking the boundary of the Arabian plate. The Red Sea and the Gulf of Aden are probably the oldest segments of the rift system, starting with its initial uplifts and doming of the crust, probably in the Oligocene. Initial volcanism is evident as early as the Eocene (e.g., Trap series), producing widespread lava. In the Miocene, thick flood basalts produced by large shield volcanoes filled the proto-rift in the Afar region. A highly active rifting phase followed in the Miocene and produced accumulation space for extensive sedimentation of the erosional material from the rift shoulders and the rift volcanism. Sedimentation was always interrupted or accompanied by flood basalts and other volcanic eruptions, changing the landscape and sedimentation environments within the basins.

There is no doubt that due to the spreading process, the EARV witnessed some habitat changes in eastern Africa. Faulting, uplifts, and subsidence support
the development of all common fluvial processes, with meandering and braided rivers, flood plains, alluvial fans, oxbow lakes, and natural levees. Major rift lakes, like Lake Turkana, developed permanent water sources during long-term transgression phases. Regression/transgression cycles are evident through changes in sedimentary formations.

11.3.1 Afar depression

The Afar Depression in Ethiopia (Figure 11.2) is one of the world’s hotspots in two ways. The temperature can climb up to more than 45°C during daytime in the endless plains of the Afar, and fieldwork is a great challenge in the extreme African sun. Still, for paleoanthropologists and paleontologists who deal with the evolution of early humans, this investigation can be of great interest since the area of about 150,000 km² bears some of the richest hominid sites in the world. In that

Figure 11.2
The outlines of the Afar depression in the northeast of Ethiopia draw a triangle of about 150,000 km². This huge basin contains fossiliferous sediments ranging in age from the Upper Miocene to recent times. The most famous hominid localities in the Afar triangle are Hadar and the Middle Awash area. The Omo Valley is located far south in the main rift, where the Omo river crosses the border into Kenya. The fossil-rich area of Koobi Fora belongs to the Lake Turkana localities in Kenya, where thick sediment deposits surround the recent Lake. Olduvai and Laetoli are positioned within the eastern branch of the Earl, while the Chad Basin reflects an intracratonic depression about 2,500 km west of the Great Rift Valley with widespread deposits of the ancestral Lake Chad.
context, the Afar Depression contains fossils from the earliest time interval of humankind, 5–6 Ma, right up to the youngest.

Since the beginning of the 1970s, the Afar Triangle has been in the spotlight of international paleoanthropological field research. Numerous hominid findings, like the skeleton of the famous “Lucy,” come from here. Paleontological work in Ethiopia started in 1902, when the Frenchman Robert de Bourg de Bozas discovered fossil-rich deposits in the lower Omo Valley north of the Kenyan boundary (Figure 11.2).

Nevertheless, the first fossil hominid from Ethiopia, a lower jaw, was discovered only in 1933, in a cave close to Dire Dawa in the east. Likewise in 1933, the French paleontologist Camille Arambourg led an expedition to the fossiliferous sediments of the Omo river (Arambourg 1933). Although no hominid remains were discovered during the fieldtrip, the team collected numerous animal fossils (Arambourg 1947). In 1967, an Ethiopian–American–French–Kenyan Team under the direction of Clark Howell and Yves Coppens, and with the collaboration of Camille Arambourg, started the intensive search for hominid fossils in the Omo region (Arambourg et al. 1967; Arambourg and Coppens 1968a, b; Coppens et al. 1976). Up to 1973, they recovered several hominid remains in the Usno, Mursi and Shungura formations in the Omo River Basin. This initiated a “hominid-rush” in Ethiopia, which continues today.

When the French geologist Maurice Taieb in 1970 announced the discovery of fossil-rich deposits at Hadar, further north in the Afar depression, the search for hominid remains shifted into the Afar region (Taieb et al. 1972, 1974). It was at Hadar that Donald Johanson and his team found the most complete A. afarensis skeleton in 1973. Inspired by a Beatles song, they named it “Lucy” (Johanson and Edey 1981). From 1975 to 1978, the American geologist Jon Kalb explored with his colleagues of the “Addis Abeba Rift Valley Research Mission in Ethiopia” (RVRME) the sediments in the “Middle Awash” region (Kalb et al. 1982a, b), where they have documented one of the best known lithological sequences in the Afar Triangle containing fossil evidence of human evolution. The sediments cover a time-span of more than 6 Myr. Intercalated volcanic ash and lava horizons permit the absolute dating of sandwiched river and lake deposits, and thereby provide a unique insight into the evolutionary history of humankind. Since the early 1990s Tim White and his “Middle Awash Research Project” have investigated successfully in these deposits. They have collected a large mammal assemblage including numerous hominid fossils, like the first remains of Ardipithecus ramidus (White et al. 1994). Since spring 2000, the international PAR-Team (Paleoanthropological Research Team), under the direction of Horst Seidler, has investigated deposits further south of the “Middle Awash” in a fossil-rich area in the Somali region, called Galili, about 100 km
north of the Awash railway station and town in the vicinity of the rift shoulder (Macchiarelli et al. 2004).

11.3.2 Central Rift

Further South in the EARV, in the Turkana Basin of northern Kenya, Richard Leakey and his team started to explore the eastern shore of Lake Turkana from 1968 through the early 1970s (Leakey and Leakey 1978), while investigations in the Omo River Valley were continuing. They surveyed the areas in the vicinity of Koobi Fora (Figure 11.2), a place where fossil bones were reported as early as 1940, and mentioned by the District Commissioner of Marsabit to Dr. L.S.B. Leakey, Richard Leakey’s father (Leakey 1978). The Koobi Fora Research Project collected fossils including many hominid remains from Plio-Pleistocene lake, river and flood plain silt, and sand deposits that are bordered by Miocene volcanic lava in the east and south, and by the recent Lake Turkana in the west.

Extensive volcanic activity accompanying the rifting process along the major axis of the rift valley forms depositional bodies with material from ash rains and lava flows. Those tuffs, basalts, and ignimbrites are important marker horizons intercalated in the sediment successions. Radiometric dating allows the determination of their absolute age and therefore also of the sandwiched fossil-bearing sediments at many hominid sites, in a region running from north of Lake Turkana in the Omo Valley, along the eastern and western shoreline, and into the southwest at Kanapoi and Lothagam. The sediment succession tells a story of transgression and regression phases during the development of the great graben. Today sediments of different age outcrop at the same level alongside them is due to small scale tectonics that produces uplift and subsidence of single blocks leading to a patchwork of sedimentary deposits. To sort the sediments into a logical lithostratigraphic column at a particular fossil locality is one of the many challenges for sedimentologists reconstructing the sedimentary settings. It took many years to reconstruct the development of the sedimentary bodies deposited during the last 6 Myr at Lake Turkana.

Further south in the EARV, the axis of the major graben seems to be nebulous. On a larger scale, the continental fracture in the earth’s crust splits in northern Tanzania into western and eastern branches, forming a large island structure between that holds an intracratonic basin, a large depression with Lake Victoria in its centre. The western branch of the EARV, with its northern deposits at Lake Albert in Uganda, has also produced a rich fauna, eroding from lake beds and river deposits from the Upper Miocene onward (Pickford et al. 1993).
So far no hominid fossils have been discovered in these sediments, whereas in the southern part of the eastern branch the fossil localities of the famous Olduvai Gorge in northern Tanzania have produced many hominid remains. In the vicinity of Olduvai, a remarkable magmatic province, with the Ngorongoro caldera, Lemagrut, Sadiman, and Oldeani volcanoes, produced immense amounts of ash during Plio-Pleistocene times, including the thick volcanics that mark the base of the Olduvai succession. The volcanic eruptions supported the creation of a fossil site that seems to be unique in the EARV. Most likely the oldest volcano, Sadiman (K–Ar age of 3.7 Ma), was the source of the volcanic sediments of the Laetoli region (Hay 1987). The distinctive geochemical composition is compatible with the Laetolil Beds, while Lemagrut and Ngorongoro produced lavas of a different petrology. The fossiliferous Laetolil Beds, close to the village Endulen, were discovered by some local Masai. Erosional processes unearthed several hominid remains, and in addition a rich fauna was discovered. The first hominid remains at Laetoli were collected by a German explorer, Kohl-Larsen in 1939, 4 years after the first visit to Laetoli of Mary Leakey. She traveled again to Laetoli in 1959 (Leakey 1987), while she and her husband Louis were excavating in the sediments of the famous Olduvai Gorge in the North. Later in the 1970s, Mary Leakey discovered one of the most remarkable pieces of evidence for the upright gait of early hominids: a footprint trail in a volcanic ash deposit. The lowermost sediments, the Laetolil Beds, were deposited on an uplifted peneplain prior to movement along the Eyasi Fault (Hay 1987), a large fault creating the steep Lake Eyasi cliff. Some modern inselbergs give evidence of the uneven surface of the peneplain, where the sedimentary deposits in the valleys mark the paleodrainage and point to east-west as the major flowing direction. Obviously, the steep Eyasi fault did not exist at the time when the water-laid deposits developed (Hay 1981), because today the river systems in the south flow more or less perpendicular to the Eyasi fault. The Laetolil Beds deposits are divided into dominantly water-laid tuffs in the south, with the addition of extensive aeolian tuffs in the north. In the upper sequence some lava flows and clay deposits occur. In recent times doming and resulting uplift led to erosion in the Laetoli region and to the exposure of the stratigraphic sequence of fossil-rich sediments.

11.4 Chad Basin

While today water erosion and fluviatile deposition during short and heavy rainy seasons is the most active land-forming process in the eastern African savannah, the Sahara desert is dominated by wind erosion and dune deposition. Brunet
et al. (1995) reported the first *Australopithecus* remains far west of the EARV from the desert of central Africa, more than 30 years after Coppens (1966) announced the first hominid discovery in Chad. Since 1994 the Mission Paléoanthropologique Franco-Tschadienne, led by Michel Brunet has explored Miocene and Pliocene deposits in the Djurab Desert of northern Chad. The deposits are located in a large intracratonic basin, which includes modern Lake Chad in the southern subbasin and the Chad lowlands in the northern subbasin (Vignaud et al. 2002). Fossiliferous sediments in the basin have been known since 1960, when Coppens reported Quaternary fossils from Koro Toro.

Recent aeolian deflation in the northern subbasin formed the Djurab Desert, with arid conditions, while the southern depression, under semiarid to wet conditions, comprises the latest lacustrine episode in the region. A “Mega Lake Chad” existed in Holocene time, but progressive desert extension of the Sahara toward the south reduced the water column of Lake Chad to its present shallow water situation. An average water depth of 2–4 m can be measured today and must be compared to a maximum depth of 180 m during ancient times. The basement of the Chad Basin is built of Precambrian rock and forms a large depression which is filled with lacustrine, fluviatile, and lake sediments. The fluviatile facies is described by flooding channels, probably deposited during torrential rainfalls because no mature river system, like meandering or braided channels, is reported (Vignaud et al. 2002).

In the northern subbasin, extensive aeolian sands contain well-sorted quartz grains, frequently formed as dunes and shifting sands, since Upper Miocene times. The fossil content, including rich fish remains, crocodiles, and semiaquatic mammals, like hippos, gives evidence of a permanent water source during the time when *Sahelanthropus tchadensis*, the oldest known hominid, lived probably in a gallery forest along the shoreline of Proto-Lake Chad. The so-called anthropotheriid unit of the *Sahelanthropus* site is interpreted to be a shallow perilacustrine environment and consists of a well-sorted and well-cemented sandstone. It yielded all the terrestrial vertebrate remains (Vignaud et al. 2002).

However, the desert already existed in the vicinity and produced sedimentary material through aeolian deflation that gradually covered the lake floor and also animal carcasses. Along the flat margin of the ancient lakes, drainage systems developed during rainy seasons. Floods reworked the aeolian deposits surrounding the lake. Temporarily thin soil layers developed on floodplains, as confirmed by root casts developed in the major fossil layer at the *Sahelanthropus* locality Toros Menalla (Vignaud et al. 2002). The sedimentary situation in the Lake Chad Basin is controlled by transgression and regression phases of the lake and the Sahara desert.
11.5 South African caves

In South Africa, the famous hominid sites of Sterkfontein, Swartkrans, Kromdraai, and Makapansgat (Figure 11.3) are formed in a very specific geological setting, compared with the eastern African hominid localities. The fossil hominid-containing sediments accumulated in caves developed in Precambrian dolomite limestones, in Plio-Pleistocene times, through extensive karstification. The cave limestones belong to the Malmani Dolomite, which is part of the Transvaal Supergroup (Eriksson et al. 1976). The age of the Malmani dolostones, deposited in the intracratonic Transvaal Basin, is considered to be between 2.5 and 2.6 billion years (Button 1973). The thickness of the deposits reaches 1,450 m, e.g., in the Sterkfontein area (Eriksson and Truswell 1974). A large sedimentary hiatus from the Precambrian to the Late Tertiary deposits is present. Abundant faulting and folding of the dolomite limestone makes determining the exact stratigraphic position of the basic cave material difficult. The occurrence of stromatoliths in the Makapan Valley led to the idea that at least some of the limestone sediments had been formed in the intertidal zone (Eriksson et al. 1976) near the shore line of the ancient sea.

The initial cave development probably followed the fracture pattern in the dolomite rock, and extensive and deep karstification took place due to groundwater level changes. A typical feature of the Transvaal karst is the occurrence of a three-dimensional hyperphreatic maze of fissure passages (Martini et al. 2003), although large caverns did develop. As a result of erosion, cave ceilings collapsed and opened larger chambers. Carbonate solutions and mineralization built up thick travertine layers on the floors. The rich travertine deposits attracted miners at the end of the nineteenth century because of their pure calcium carbonate content. On the other hand, the carbonate is responsible for the consolidation of clastic sediments that filled up caverns through openings from the land surface. Sand, chert, dolomite, quartzite materials, and also bones were washed down into the caves. Winds probably brought fine grains, following the law of gravity. Possibly several transporting agents led to the high bone accumulation at some localities in the cave systems. Some of the caverns were completely filled up with exogenic material, and their sediments concreted to cave breccias with a fine-grained matrix and carbonatic cement. Differences in color and grain size may indicate different modes and phases of sedimentation. To access the bones, which are baked in the breccias, demands sophisticated physical and chemical preparation techniques.

Gravity and water transport, together with typical processes like collapses, solution, and remineralization, are responsible for the complex geological setting
of many of the caves. The extensive lime works in the South African caves brought thousands of bone fragments to light, although blasting operations destroyed many natural features of the caves. Consequently, reconstruction of the diagenesis of the South African cave sites was a real challenge and many aspects still need

Figure 11.3
The caves at Makapansgat belong to a large Precambrian dolomite formation (above) showing profound karstification and sedimentation during Plio-Pleistocene times. Limestone cavities (below) are filled with travertine and characteristic carbonatic bone breccias. Mining for carbonates hollowed the filled cavities and brought thousands of fossils to light. The preservation of the fossils differs from sites in the EARV due to very different processes of site formation.
further investigation. The analysis of the taphonomic history of bone accumula-
tions at the South African cave sites needs detailed on-site observations and also
lab work. Bob Brain and his team investigated many years at Swartkrans, before
he came up with his last model of cave development, where he proposed nine
diagenetic steps (Brain 1993). The formation started with a probably Miocene
cavern below the level of standing water. After the opening of the cave, surface
sediment began to accumulate inside the cave. The interpretation of the fossilif-
erous ‘pink breccia’ of the Outer Cave, which was shown to be an infilled
remnant, the Hanging Remnant Unit of Member 1, proved to be especially
time consuming.

Swartkrans Members 1–3 yielded inter alia the remains of Australopithecus
robustus, which is likely to have an age of 1.8–1 Ma. Members 4–5 are Middle
Stone Age and ca. 11,000-year-old, respectively.

Extensive investigations at Swartkrans and other South African cave sites lead
to conclusive models about the development of the deposits and their fossil
content in time and space. The experience and strategies used in the past provide
the knowledge and tools to further explore the karstified limestones in South
Africa and at other localities.

11.6 Conclusions

Although it seems to be clear that the chance of finding hominid fossils is limited
by the factors mentioned earlier, there is no doubt that many fossils still await
unearthing, either by erosion or by man. The types of sediments and the
geological contexts likely to yield hominid fossils are known. We just have to
look for the right deposits. So far, early hominids have only been discovered in
eastern and southern Africa, with the exception of the Chad Basin in central
Africa. This is probably due to the auspicious geological setting and time repre-
sented in the EARV, rather than reflecting the paleobiogeographic distribution
pattern of early hominids, although the occurrence of permanent freshwater
sources, represented, e.g., by large rift lakes, probably attracted early hominids,
because they were not capable of carrying a larger amount of water from one
location to another.

No doubt the hominid richness of the Rift sediments is unique altogether.
There is still a high potential to recover more remains at long known places
because erosion is always at work and the immense deposits in the EARV are far
from fully explored. Huge areas, for instance in the Afar Triangle and in other
places, have never been surveyed for fossils. New techniques like satellite imagery
with a resolution of a few meters on the ground are of tremendous help for
exploration work. Additionally, airborne survey can provide access to remote places such as those in the Danakil depression in the northern Afar. Nevertheless, extensive studies of satellite images will almost certainly discover new fossiliferous localities in smaller-scaled graben and basin structures somewhere in central, western or southwestern Africa. It seems just a matter of time until the first early hominid is reported from the other side of the African continent.

**Acknowledgments**

I especially thank Winfried Henke, Hartmut Rothe and Ian Tattersall for giving me the opportunity to contribute to the Handbook of Paleoanthropology. Further, I would like to thank Ian Tattersall, Winfried Henke and my colleague Oliver Sandrock for their helpful comments and for reviewing a draft version of the manuscript. Many thanks to Christine Hemm for help with the figures.

12 Paleoclimate

Keith Alverson

Abstract
This chapter provides a brief overview of the dynamics and pattern of climate variability from the Plio-Pleistocene to the modern day including Quaternary ice ages, millennial scale variability, abrupt climate change, and the Holocene. Selected examples of terrestrial, marine, and cryospheric archives of paleoclimate information and the proxy climate information that can be quantitatively extracted from them are presented. Although the primary focus of the chapter is climate variability itself, a few examples of the past interactions between climate and human societies are also presented. The chapter concludes with some speculative comments on lessons that can be drawn from such studies of the past with relevance to modern day concerns.

12.1 Introduction
In 2004, three major hurricanes crossed Polk County, Florida. Local people’s lives were changed in dramatic and memorable ways. The events were also felt on a national scale, affecting a number of large institutions such as the federal government and the insurance industry. From the perspective of residents of Polk County, 2004 was a remarkable climatic year. But from the temporal perspective of centuries, or the spatial perspective of the entire planet, this series of events is an insignificant footnote.

For most of human history, individuals and societies have experienced climate on local space scales and timescales of a few generations at most. These scales of human perception of climate are very different from those inherent to the climate system itself. The climate system is globally interconnected and varies on all timescales, with the most energetic variations on timescales of 100,000 years and longer. In part as a result of this disparity of scales, understanding the influence of climate on the evolution of Homo sapiens and the development of human societies is not an easy task. However, it is unquestionable that enormous climatic changes occurred on the timescales of human evolution and societal development and, at times, played a role in these processes.
This chapter focuses primarily on past climatic variability during the Quaternary including both reconstructions of past climate variability and some hypotheses seeking to explain the dynamics of this variability. In light of the likely interests of readers of this paleoanthropological handbook, a few examples of interactions between past climate variability and human societies are highlighted. The chapter begins with a brief discussion of the climate of the Plio-Pleistocene, followed by discussion of Quaternary ice ages, millennial scale variability, abrupt climate change, and the Holocene. It concludes with some speculative comments on lessons for modern day concerns that can perhaps be drawn from investigations of past climatic variability and its influence on humans.

12.2 Pre-Quaternary climate

Pre-Quaternary climate and environment conditions are not discussed in detail in this chapter but are included briefly to provide a general context for the subsequent sections. For longer time perspectives, including the paleoclimatic context of hominid evolution, the reader is referred to the chapter 16 by Etter (Patterns of Diversification and Extinction) of this handbook. One of the best indicators for global climatic conditions on timescales of millions of years is provided by the ratio of oxygen isotopes recorded in shells of deep-sea dwelling foraminifera preserved in deep-sea sediments. Figure 12.1 shows one such record from a deep core drilled in the equatorial Pacific (Mix et al. 1995a, b). Such records are influenced by a number of local variables, including for example seawater temperature, but are nonetheless thought to provide an estimate of global atmospheric temperature and the volume of water stored in continental ice. Thus, Figure 12.1 illustrates a time history of the transition from relatively warm, conditions of the late Miocene with little or no Northern Hemisphere glaciation, into the predominantly cold and glaciated, but highly variable, conditions of the late Quaternary.

Records such as the one shown in Figure 12.1 highlight a number of intriguing questions about the nature and variability of pre-Quaternary climate dynamics. The primary driver of both the overall trend and much of the variability is thought to be the pattern of solar radiation incident on the Earth. Variations of the eccentricity of the Earth’s orbit, from more circular to more elliptical, influence the degree of seasonality of climate, with opposite forcing in the northern and southern hemispheres. Over the past 5 million years, the eccentricity in earth’s orbit varied quasiperiodically on timescales of 413,000 and 100,000 years. At the same time, changes in the tilt of the earth’s axis, or
obliquity, varied with a fairly periodic oscillation on a timescale of 41,000 years. The effect of obliquity changes is primarily on the amount of solar radiation reaching high latitudes and has the same sign in both hemispheres. Finally, precession of the equinoxes, i.e., changes in the location of the earth within its elliptical orbit relative to the seasons varies with a primary period of about 22,000 years. Individual orbital forcing terms are not independent of one another, for example, the influence of precessional changes is coupled to eccentricity variations, the location of the earth within its orbit at a certain time of year being most important at times when the orbit is most elliptical.

Although changes in orbital parameters are the main external driver of paleoclimatic changes over the past several million years, internal dynamics of the climate system itself are far more important if one is interested in the actual temporal and spatial patterns of climatic change. For example, orbital changes do not explain why the global climate system responded primarily to the relatively weak 100,000 year forcing associated with eccentricity during the Quaternary, but to the 41,000 year forcing associated with obliquity during the late Pliocene and early Pleistocene. Nor do they explain the long-term cooling trend starting in the early Pliocene. Relevant processes internal to the Earth system that influence the global climate state on these timescales include concentrations of atmospheric greenhouse gases, the pattern and degree of reflectivity of the earth associated with changes in the biosphere and cryosphere, and orographic changes associated with tectonics.
One example of climatic variability driven primarily by a combination of external and internal system dynamics is the development and variability of the East Asian Monsoon. Conveniently, one of the most well-preserved terrestrial archives of climatic change over the Plio-Pleistocene come from loess deposits in central China. These widespread 100–300-m thick deposits are characterized by alternating layers of loess dust and interbedded paleosols. The loess was deposited during relatively cool periods dominated by northerly winter winds while the paleosols reflect pedogenesis associated with relatively warm conditions and the moisture bearing summer monsoon. The time series of monsoonal fluctuations captured in loess records has been extensively correlated with deep-sea oxygen isotope records and, not surprisingly, cool dry periods of strong loess deposition tend to correlate fairly well with periods of high global ice volume. As shown in the Lingtai loess section in Figure 12.2 (An 2000), magnetostratigraphic measurements suggest an onset of loess deposition, and thus the inception of the East Asian monsoon, may have been as early as 7 Ma. The uplift of the Tibetan Plateau, a primary driver of continental aridity, may have already been substantial at that time. Loess records also indicate evidence for a later pulsed uplift in the Tibetan plateau around 3.5 million years ago, again consistent with the onset of strong northern hemisphere glaciation indicated by marine records.

Although intriguing, when thinking about paleoclimate records of the Plio-Pleistocene such as those shown in Figures 12.1 and 12.2, it is important to keep in mind several substantial caveats. Because there have been an enormous number of poorly understood processes involved in the development, preservation, and measuring of these archives, there remains enormous uncertainty in interpreting deceptively precise measurements of material properties such as oxygen isotopes and magnetic susceptibility in terms of anything beyond a qualitative impression of climatic parameters such as global temperature, ice volume, or East Asian monsoon strength. Quantitative estimates, or uncertainty ranges, provided in units such as temperature in degrees centigrade or ice volume in cubic meters, are usually, for good reason, avoided altogether. A relative paucity of climate proxies on these timescales makes it difficult to independently verify many of our interpretations of those we do have without employing circular logic. For example, the records are not absolutely dated, other than perhaps at a few critical points, and are usually tuned either to other records or orbital parameters, leading to obvious logical circularity. Although these types of problems are common to all paleoclimatic reconstructions, on all timescales, they become substantially less severe for Quaternary reconstructions due, largely, to the availability of ice cores.
Figure 12.2
Magnetostratigraphy, lithology, magnetic susceptibility, and grain size variations of the Lingtai loess section (35°04′N, 107°39′E) covering the past several million years. A shift to stronger monsoon occurred approximately 3.5 million years ago. Marked variability on 41,000-year timescales in the early Pleistocene followed by dramatically dominant 100,000 cycles of the Quaternary ice ages is also evident (An 2000).
12.3 Quaternary glacial–interglacial cycles

The climate of the last several hundred thousand years has been dominated by enormous glacial–interglacial oscillations on a period of about 100,000 years. During glacial maxima, vast expanses of the Northern extratropics, essentially all of modern day Canada for example, were buried under ice, whereas during relatively brief interglacial periods high latitude northern hemisphere was warmer, with glaciers restricted to high altitudes and extreme polar environments. From a paleoclimatological perspective, we are rather lucky that interglacials have not been a bit warmer and thus still supported year round ice in polar areas, notably Antarctica and Greenland. It is deep cores from these ice masses that provide continuous, quantitative records of temperature and atmospheric properties. One unique property of ice cores as a tool for paleoclimatic reconstruction is that, in addition to standard “proxy” measures of paleoclimate, such as inferring past temperature from oxygen isotope measurements, ice cores also trap actual atmospheric samples from past times in bubbles in the ice. Measurements of properties of these tiny gas samples, such as carbon dioxide concentration, provide extremely powerful evidence for paleoclimatic analysis, analogous to fossils in the archeological record.

The longest ice core records come from Antarctica, where as many as eight glacial–interglacial cycles are reflected over a continuous seven hundred thousand year record. Deuterium, an isotopic proxy for temperature, as measured in one such core is shown in Figure 12.3 (EPICA Community Members, 2004). At the writing of this chapter, a carbon dioxide record over the full length of this record had not yet been published.

Over the past few glacial cycles, a wealth of paleoclimate evidence from both hemispheres provides a coherent picture of massive 100 thousand year glacial–interglacial oscillations. On these timescales, high latitude northern hemisphere summer insolation is the most plausible primary driver of global atmospheric temperature oscillations, depending on location and with substantial uncertainties depending on the method of reconstruction, in the range of 2°C–20°C. Dramatic well-documented associated changes occurred in the terrestrial biosphere and landcover, affecting for example surface reflectivity and global water pathways; in ocean surface temperatures, affecting greenhouse gas uptake; and in atmospheric dust and greenhouse gas concentrations, affecting radiation balance. Such changes are among many strong feedback mechanisms that potentially contribute to explaining why relatively minor radiation receipts over a relatively miniscule area should have resulted in a substantial response over the entire globe.

A compendium of a few sample proxy records providing a flavor for nature and magnitude of climatic and environmental on glacial–interglacial timescales.
in both hemispheres is presented in Figure 12.4 (Labeyrie et al. 2003). From an anthropological perspective, some of the most intriguing changes include oscillations in global sea level associated with trapping of water in continental glaciers and changes in terrestrial ecosystems associated with changes in temperature and moisture availability. For example, the sea level decrease of well over 120 m at the last glacial maximum lead to formation of a land bridge facilitating relatively easy human migration from Asia to the Americas and climate change must have played a role, alongside contemporaneous hunting pressures from humans, in the well-established subsequent decline of North American megafauna.

One of the most intriguing dynamical questions associated with Quaternary ice ages is why atmospheric CO₂ varied in such tight correlation with temperature. This correlation presents an intriguing set of questions about the operation of climate, the Earth system more broadly and in particular the global carbon cycle.

Some studies seeking to address these questions have focused on what sets the upper and lower limiting values of atmospheric CO₂ concentration of roughly 180 and 300 ppm during glacial and interglacials, respectively (Falkowski et al. 2000). Slowdown of the terrestrial ecosystem during glacial periods leading to reduced ability of the terrestrial biosphere to take up carbon has been implicated as a possible explanation for the lower bound, while the upper bound might simply be a response to global cooling associated with glacial inception after relatively brief interglacial periods, with oceanic processes setting the range and frequency of variability on timescales longer than centuries.

Figure 12.3
Deuterium, a proxy for temperature, over eight glacial–interglacial cycles as measured in the EPICA Dome C ice core (EPICA 2004)
Several oceanographic mechanisms have been proposed to explain, either individually or in concert, the decrease in atmospheric CO₂ associated with glacial states as compared to interglacials. These include: increased efficiency of the “biological pump,” in which net carbon uptake, especially by the high latitude marine biosphere, is increased relative to upwelling fluxes, changes in the rate of ventilation of deep water in the Southern Ocean, decreased global thermohaline overturning circulation, enhanced air–sea exchange in the northern Atlantic, decreased air–sea exchange in the Southern ocean due to enhanced sea ice cover, increased solubility of CO₂ in colder seawater, and a middepth chemical divide separating watermasses with low and high CO₂ concentrations (Pedersen et al. 2003).

Some studies suggest simple, albeit highly specific, mechanisms (Stephens and Keeling 2000), while others claim that all simple mechanisms can be eliminated from consideration (Pedersen and Bertrand 2000), indicating that multiple or unknown processes must be at work. In contrast, LeGrand and Alverson (2001) assert that the problem is underdetermined and that many plausible solutions therefore exist. Employing a simple inverse box model, they find several solutions. Within reasonable uncertainties, a single change in the Southern Ocean relative to their modern control simulation, for example reduced air–sea gas flux, reduced deep water ventilation, or enhanced biological productivity, can explain all of the model and paleodata constraints available for the glacial state.

What can we conclude about the global carbon cycle? Clearly, the upper bound of around 300 ppm that has marked atmospheric CO₂ variability over at least the past 400,000 years is not an impenetrable one. It has already been shattered by modern anthropogenic inputs of fossil carbon to the atmosphere and is rising fast. Will this perturbation disrupt the system sufficiently to drag the Earth out of the attractor, marked by glacial oscillations, that it has been in during the Quaternary? Unless we understand how the system as it has operated in the past, it will remain impossible to move beyond simple conjecture based on correlation. Such conjecture is particularly tenuous when extrapolated to atmospheric CO₂ levels, such as those anticipated for 2,100, for which there is no analog in the Quaternary period for which well-dated, relatively precise paleorecords exist.

12.4 Millennial variability

Even a cursory glance at the records in Figure 12.4 reveals that climate variability on the timescale of millennia, particularly during glacial periods, is substantial, with larger oscillations reaching as much as half the size of the
Figure 12.4
Climatic proxies from both hemispheres over four glacial cycles as recorded in a variety of paleoclimate records. (a) Summer insolation (21 June) at 65°N. (b) North Atlantic Sea surface temperature (SST) record from deep-sea sediment core at ODP site 980. (c) South Indian ocean SST derived from foraminiferal transfer functions, from deep-sea sediment core MD 94-101. (d). Atmospheric CO₂ and temperature estimated from δD from the Vostok ice core. (e) Summer insolation (December 21) at 65°S (Labeyrie et al. 2003)
The glacial–interglacial signal itself. However, it was not until the mid-1980s that this variability was widely recognized in the paleoclimate community, initially due to the advent of high resolution ice core records from Greenland (Dansgaard et al. 1984) later corroborated by interpretation of alternating layers of “ice rafted debris” in deep-sea sediment records from the North Atlantic ocean (Heinrich 1988). In honor of these early discoverers, the half a dozen or so larger climatic swings between 60 and 15 ka are commonly referred to as “Heinrich events” while more than 20 smaller events are generally called “Dansgaard–Oeschger (D/O) events.” Moreover, the events themselves seem to be grouped in cycles, sometimes called Bond Cycles, beginning with the most severe and gradually declining in amplitude until the next multiple cycle is initiated.

By combining the stratigraphic record of these rapid D/O oscillations with attempts to model the mechanisms responsible, the dominant hypothesis to emerge sees the events as a product of the instability of the ice sheets that girdled the North Atlantic. Rapid discharge of ice into the ocean is thought to have reduced surface seawater salinity to the point where North Atlantic Deep Water (NADW) formation was inhibited, thereby shutting down the related transport of heat into the region by the large scale overturning circulation of the North Atlantic ocean. This cut-off of NADW formation may then have so modified ocean circulation as to have influenced climate on a global scale. Such a hypothesis is consistent with the antiphase relationship between Greenland and much of Antarctica often referred to as a bipolar “see-saw.”

It seems possible that the variations in amplitude of the cold “swings” reflect changes between iceberg surges reflecting instability of the Fennoscandian ice sheet, with a relatively more rapid response time, and the Laurentide Ice sheet with a longer response time. Surges of the latter are thought to have been responsible for the most extreme events, those that gave rise to the main “Heinrich” IRD layers. The periodicity of the D/O events is not regular, and no credible external forcing mechanism has been proposed. The bipolar antiphase relationship demonstrated for the major D/O events suggests that they are largely the product of cryosphere-ocean dynamics.

In the decades following the initial discoveries the same millennial events seen in the northern North Atlantic region have been found to be widespread, with clear evidence in such diverse locations as Chinese loess deposits and stalagmite isotope records, deep sea sediments from the Cariaco and Santa Barbara Basins, and even Antarctic ice cores. A compendium of a few such proxy records providing a flavor for nature and magnitude of climatic and environmental on millennial timescales in high and low latitudes and both hemispheres is presented in Figure 12.5 (Labeyrie et al. 2003). The global nature of these events has lead to further questions and refinements regarding the
possible atmospheric and oceanic mechanisms for transmitting these signals around the globe, for example, through influence on the Asian monsoon systems in the case of Chinese records, or the rate of ventilation of intermediate depth waters of the Pacific, in the case of the Santa Barbara Basin record. However, changing rates of overturning circulation driven by fresh water fluxes in the northern North Atlantic remain a widely accepted, plausible hypothesis for the primary driver of this variability.

12.5 Abrupt climate change

One of the most exciting new developments within the area of global change science has arisen from the growing body of paleoclimatological evidence for rapid changes in the climate system. Until recently it would have been hard to imagine that the global climate, together with other aspects of the Earth system to which it is intimately linked, could have undergone repeated oscillations on millennial timescales as described earlier, let alone that the most dramatic of these “switches” occurred within a matter of decades, with major consequences for temperatures, hydrological regimes, plants, and animals that were at the very least hemispheric in their extent. The evidence now available provides a fascinating insight into the climatic backdrop to the development of human societies in the past. It also highlights one of the major challenges for the future. If the potentially disastrous impacts of climatic “surprises” like the ones that have already been well documented from ice core and sediment records are to be avoided in the future, research devoted to deepening our understanding of abrupt changes in the past is of paramount importance.

Any definition of “abrupt” climate changes is necessarily somewhat subjective, as it depends in large measure on the sample interval used in a particular study and the pattern of longer-term variation within which the sudden shift is embedded. Here, I make no attempt at a general definition but focus attention on two examples of rapid transition found in the paleorecord from the geologically recent past, glacial terminations and the Younger Dryas.

12.5.1 Glacial terminations

Marine, polar ice core, and terrestrial records all highlight the sudden and dramatic nature of glacial terminations, the shifts in global climate that occurred as the world passed from dominantly glacial to interglacial conditions. The dramatic nature of these terminations is immediately evident in Figure 12.4.
One metric for the rapidity of these glacial terminations is provided by very well-documented rates of global sea level rise. During glacial terminations, sea level rose roughly 100 m in less than 10,000 years, a mean rate of roughly 1 m per century. This is at least an order of magnitude faster than anything that has been suggested for future climate change scenarios associated with global warming (Houghton 2004). In addition, during the last interglacial, sea level was about 20 m higher than today. Thus, both the magnitudes and rates of sea level rise have been significantly larger than either those that have been documented in recent years or predicted for future climate change scenarios.

Because the melting of large, northern hemisphere, continental ice sheets which no longer exist is thought to be the reason that past rates of sea level rise were so large, one might be tempted to think that understanding the controls of sea level on these timescales is not relevant to the future. There are two strong arguments against this line of reasoning. First, and most importantly, large and growing coastal populations in the modern day are highly vulnerable to sea level rise, whereas during the last interglacial no such settlements existed. Thus, even a much more gradual, smaller amplitude sea level rise occurring today will have much greater human impact than those of the past. Furthermore, extant ice sheets on Greenland and Antarctica represent fresh water storage equivalent to many meters and many tens of meters of sea level, respectively. The possibility of rapid destabilization of even a small part of these ice sheets in the future, although less likely than many other climate change predictions, cannot be excluded from consideration. Thus, an understanding of the dynamics of large ice sheets... gained through investigation of their behavior in the past, may be important for our future.

Given the growing, and increasingly urbanized, coastal population and the great potential for nonlinear “threshold crossing” response of coastal zones and the ecosystems they support to sea level rise, there is an urgent need to understand the processes driving and responding to sea level rise on timescales from decades to millennia. Many of these processes, such as postglacial rebound of continental plates, continue to effect sea level change today. The past record of sea level change is thus highly relevant to its likely future course.

Although sea level is a broadly global property, two features of glacial terminations tend to qualify the view that they are a single, rapid, globally coherent, monotonic process. When the inferred temperature change in Antarctica and Greenland are carefully synchronized on the basis of their records of changing atmospheric methane concentrations, it is clear that during the course of the warming trend from Glacial to Holocene, the record from Antarctica leads that from Greenland; moreover during the period of warming, the sharp fluctuations in temperature that mark the Greenland record in particular, are largely in
antiphase with the changes in much of Antarctica. Recent high resolution Urani-
umum Thorium dating reinforces the idea of an Antarctic lead, since it suggests
that the penultimate glacial termination occurred $135 \pm 2.5$ ka (Henderson and
Slowey 2000). This date precedes the Northern Hemisphere June insolation peak
by nearly 10,000 years. Thus, although consistent with primary deglaciation
forcing by insolation levels in the southern hemisphere, or the tropics, this
evidence runs counter to the view that insolation forcing at high northern
latitudes was the initial trigger for deglaciation. Any concept of a rapid shift
associated with glacial terminations thus has to be qualified by the realization that
the rate of change is not uniform over the whole globe and that the oscillations
that are superimposed on the trend are not globally parallel in sign.

12.5.2 Younger Dryas

The Younger Dryas marks the final stage of the last glacial termination, the
transition to the Holocene. The transition out of the Younger Dryas cold reversal
into the Holocene is one of the most well-studied rapid climate transitions, both
in terms of regional climate expression, primarily in the North Atlantic and
Europe but also elsewhere, but also its influence on ecosystems (Amman and
Oldfield 2000). Some sense of the suddenness of this transition may be obtained
from the record of ice accumulation and temperature in central Greenland
shown in Figure 12.6 (Dansgaard et al. 1993). At this location, most of the
transition, a near doubling of snow accumulation rate and a temperature shift
of around $10^\circ$C, was accomplished within a decade or less. By any standards,
this is a truly dramatic, abrupt shift in climate, yet the generally accepted external
forcing, an increase in solar irradiance, was relatively modest and certainly
gradual. Again, we see external forcing pushing the Earth system over some
crucial threshold beyond which internal dynamics can generate extremely rapid

Figure 12.5
Millennial climate variability during the Last Glacial period (60–15 ka). The timing of the
large Heinrich events is indicated by the labels H2 to H5, while the vertical gray lines mark

responses through a range of, as yet poorly understood or quantified, feedback mechanisms.

### 12.6 Holocene

It has sometimes been claimed that the stable climate of the Holocene helped the transition from hunter gather to agriculturally based and later development of modern societies to occur. This line of thinking arose, at least in part, due to the almost complete lack of variability in Greenland ice core isotope records during
the last 10,000 years as compared to the dramatic variability during earlier times (Figure 12.6). The paradigm can be criticized in two important ways. First, and most importantly, people do not live in central Greenland and second, there is now ample evidence from both Greenland and other parts of the world that the Holocene has not been climatically stable at all (Mackay et al. 2003; Battarbee et al. 2004). In addition, there are good reasons to believe that climatic variability, not stability, might be expected to lead to changing societal structures.

We know, from well-dated quantitative paleorecords, that regional hydrological change during the Holocene has been extremely large. The extent of glaciation in the Swiss Alps, for example, has been highly variable during this time, including periods when the glaciers were substantially more restricted than today. Lake levels in much of semiarid Africa have risen and fallen by 100 m on similar timescales. These large, and often rapid, climatic changes had substantial impacts on human societies, even playing a role in the demise of several civilizations including the Mayan, Akkadian, and Greenland Norse. Societies, develop, adapt, and change in response to variability, not when ensconced in a cocoon of stability. Indeed, precisely societal change and adaptation are the presept requirement, in the face of global anthropogenic change.

12.6.1 Early Holocene

Although in stratigraphic terms the Glacial/Holocene boundary is, over much of the world, a clearly recognizable and apparently synchronous feature, this does not imply that the Earth system as a whole experienced an instantaneous and complete shift. Several of the responses to the rapid changes taking place at the boundary took centuries, even millennia to complete. These include processes such as the melting of the polar ice caps, the recovery of global sea level to something approaching its present height, the recolonization of extensive areas by vegetation adapted to changed thermal and hydrological regimes, and the maturation of soils that goes hand-in-hand with increasingly stable vegetation cover where this had been absent during glacial times. Hence it is important to remember that the period was one of transitions and readjustments.

There is clear evidence from several quite widely spaced sites for a sudden climate anomaly lasting for several hundred years centered around 8,200 Br. This event shows up as a sharp decline in inferred temperature and in methane concentrations in ice core records from Central Greenland. An almost perfectly parallel change in d18O-derived temperature can be seen in the evidence from Ammersee, in southwest Germany, based on stable isotope analyses of ostracod
remains (Von Grafenstein et al. 1998). A growing number of records appear to indicate that this oscillation had a widespread effect. In terms of timing and signature in the Greenland ice cores records, it appears to be in many ways comparable to the preceding, higher amplitude D/O oscillations and some link to rapid draining of glacial lakes in North America and NADW formation may be involved (Barber et al. 1999), but there is also the possibility that the event, especially the methane anomaly, is linked to lower latitude changes in the extent of tropical and subtropical wetlands or the effects of rising sea level. Certainly, the whole of the early Holocene is marked by dramatic shifts in lake level and wetland extent in Africa and Central America.

The records of changing lake levels for a range of sites in Africa constitute dramatic evidence of the major changes in hydrology that occurred during the early Holocene. Two examples of such lake level records are shown in Figure 12.7 (Gasse 2000; Verschuren et al. 2000). Equally powerful indications of variability come from reconstructions of the changing extent of wetlands and vegetation cover in the Sahara/Sahel region and from evidence for high altitude lake level variations in the Altiplano of the central Andes. The dynamics of these dramatic, low-latitude hydrological changes are complicated by the fact that the changes in surface hydrology and vegetation have a strong feedback on regional climate. For example, without including this feedback alongside other forcing, including sea-surface temperatures, it is impossible for existing numerical models to simulate the extent of wetlands and plant cover in the Sahara/Sahel region during much of the early Mid-Holocene (Claussen et al. 1999).

12.6.2 Late Holocene

The later part of the Holocene is by far the most well-documented period of paleoclimatic history, this is largely due to the presence of numerous, independent, and well-preserved archives which can be precisely dated and measured with annual resolution. Notable among such extremely precise paleoclimatic records are documentary archives, rings from living and fossil trees, and growth bands from speleothems (cave deposits) and tropical corals, and annual accumulation layers from high altitude ice cores. Inevitably, attention focuses on the so-called Little Ice Age and Medieval Warm Period. Well chronologically constrained evidence for climate changes broadly paralleling, but rarely perfectly synchronous with, the European Medieval Warm Period—Little Ice Age sequence has been identified in records right across the northern hemisphere (Alverson and Solomina 2004) and into low latitudes—for example, in ice core records from Quelccaya Ice Cap in Peru.
Was the Medieval Warm Period as warm as the 1990s? Long tree ring chronologies are one of the most important sources of information available to address this question. *Figure 12.8* shows a recent, extratropical, treering based reconstruction (Esper et al. 2002) compared with an earlier hemispheric, multiproxy reconstruction (Mann et al. 1999) and their respective uncertainty.
estimates. The differences between these curves have been the subject of an active debate in the community. Of particular interest has been the question of whether the Northern Hemisphere average warming measured in recent decades is indeed greater than that associated with the peak of the Medieval Warm Period approximately 1000 years ago. The amount of cooling that occurred several centuries later during the Little Ice Age and whether this cooling was geographically restricted to certain regions in the extratropics is another issue of considerable debate.

Notable among many differences in the construction of the curves in Figure 12.8, the former (Mann et al. 1999) contains records from multiple proxies and from the tropics, whereas the later (Esper et al. 2002) makes use of a novel technique (Regional Curve Standardization) designed specifically to obviate the inherent loss of centennial scale variability in long chronologies constructed from a series of short, detrended records spliced together. Rather than highlighting the differences between these two curves, one might consider their similarities. They capture many of the same decadal scale events and lie at least 95% within each others’ 95% confidence limits. They both show the remarkable power of long proxy-climate records to put modern changes in the perspective of the past and to use this perspective to better understand natural and anthropogenic drivers of global change. Together, they also indicate some of the most promising areas for future research: better calibration of the growth response of trees to climatic forcing, the need to quantify the range of frequencies that can be reasonably expected to be captured by given reconstructions of past climate variability, and the need to develop long, annually resolved, quantitative, paleoclimatic proxy records from the tropics.
Studies of the relationship between Holocene climate variability and human societies have often been marked by antithetical perceptions within the social science and physical science communities (Oldfield and Dearing 2003). Archaeological and anthropological research encompass interpretations of socioeconomic and cultural change, resource use, and subsistence practices (Pringle 1997; Redman 1999), but the direct evidence for potentially damaging climate change is usually derived independently from different archives and lines of evidence (Cullen et al. 2000; Hodell et al. 2001). As a result, even where temporal correlations can be proposed between major societal changes and shifts in climate, they could be viewed as little more than coincidences. Taken to its extreme, the “cultural” view attributes major changes in past societies, even the collapse of ancient civilizations, entirely to human actions. Although human actions are clearly important, too one-sided interpretation is not supported by research which ascribes the collapse of civilizations as diverse as the classic Akkadian (Cullen et al. 2000), Mayan (Hodell et al. 1995, 2001), and Anasazi (Dean et al. 1985, 1999) cultures to abrupt and persistent climatic changes. Figure 12.9 presents a selection of paleoclimate examples where the combination of environmental and cultural history, coupled with rigorous chronological constraints, points to a strong link between the incidence of drought and the collapse of human cultures. Such studies do not discount the role of societal factors but assert that, at times, climate variability has been a critical factor influencing societal stability.

Four thousand years ago Yu the Great, founder of the first, semimythical, Xia dynasty of China is said to have spent more than a decade battling floods continuously inundating the valley of the Yellow river. According to Confucius’ Shu Jing (Book of History), written much later in the fifth century BC but supposedly collated from ancient sources, Yu’s great insight was to discontinue the practice of building ever-higher levees and dikes and instead dig a vast network channels to drain the great volumes of water east to the sea. Flooding, up until the present day, has continued to be a major concern for the region. A million people are thought to have died when the Yangtze broke through flood defenses in 1877. But flooding is not the only problem; the flow of the Yellow River has been in continual decline for the last 50 years. In 1997, the river ran dry in places during 226 days of the year. Much of China’s agriculture and population depends on water from the Yangtze and is greatly vulnerable to drought.

The proposed modern day solutions, multibillion dollar engineering projects, are not so very different from those proposed in the time of Yu the great.
One, the famous Three Gorges Dam, in addition to generating electricity, is intended to control flooding. A second, intended to ameliorate vulnerability to drought, is to divert water to the north, primarily from the Yangtze river basin, by digging a series of south to north canals in the western, central, and eastern parts of China. Will these gigantic engineering projects fulfill their goals? Will they reduce human vulnerability to climatic variability and change?

![Figure 12.9](image)

Two examples of paleorecords where the combination of environmental and cultural history, coupled with rigorous chronological constraints, point to a strong link between the incidence of drought and the collapse of human cultures. In the upper panel, drought in Yucatan, Mexico inferred from changes in the stable isotope ratios in two species of ostracod is shown to coincide with the collapse of Mayan civilization (Hodell et al. 2001). In the lower panel, a steep fall in carbonate percentage in a marine sediment record from the Gulf of Oman, representing a major episode of dust deposition, is directly linked to drought conditions associated with the demise of the Akkadian civilization (Cullen et al. 2000; Adapted from Alverson and Oldfield 2003)
The answers to these questions are a matter of much debate, but one salient fact is often overlooked in that debate. Paleoenvironmental science provides a detailed, quantitative record of human society, climate variability, and their interaction over the past several thousand years, both in the Yangtze valley region and over the rest of the globe. Such information from the past is directly relevant to questions of climate variability and human vulnerability today and therefore directly relevant to the modern debate.

12.7 Anthropocene: Implications for the future

Understanding past climatic and environmental change is clearly relevant to predicting the future. This contention is not new (Alverson et al. 2000, 2003; Alverson and Kull 2003), but a few salient examples deserve highlighting here.

- The paleorecord extends instrumental climate records thereby increasing the statistical significance of documented anthropogenic change.
- Long-term processes in the paleorecord operating on timescales of decades to millennia are still occurring and will influence the present and the future as they have in the past.
- The paleorecord contains a much fuller representation of the range of climatic and environmental variability than do either the instrumental record or numerical models.
- The paleorecord abounds with large and abrupt climate changes.
- The paleorecord includes numerous examples of the interaction between climate change in ecosystems and even societies.

Growing attention has been paid to the possible ramifications of potential future abrupt shifts beyond the range of variability on which planning and construction schemes are based and even outside the envelope of scenario future projections generated by climate models. The record of climate variability back through time reveals that such changes, often sudden, and sometimes persistent on decadal to century timescales. By the very nature of nonlinear systems, which are marked by sensitive dependence on initial conditions, such abrupt changes will remain largely unpredictable, no matter how sophisticated coupled, dynamical climate models may become. Thus, the best way to account for them is to develop scenarios based on past events.

Examples of abrupt climate events in the paleorecord are not limited to Greenland or glacial periods. Hydrological variability such as that shown in Figure 12.7, for example, includes sudden and high amplitude changes that
can be persistent for decades to centuries. Such variability lies well outside the range of instrumental records. Concepts of future environmental sustainability, water supply, and food security are limited and potentially dangerously short sighted if they fail to accommodate such evidence, especially given that these records are from regions that today experiences widespread catastrophic human casualties following on just a few consecutive years of drought. Climate variability and environmental change have played a major role in the welfare of human societies in the past, and all current indications are that their significance may be even greater in the future. The combination of high vulnerability to environmental hazards, such as floods and droughts, and continuing rapid population growth leave parts of the region under serious threat from increased variability, extreme events and future sea-level rise. Climate variability affects human welfare in a variety of ways and on a range of spatial and temporal scales. Equally, as land cover and agricultural practices change in response to evolving human needs there are important feedbacks to the climate system. The paleorecord holds vital clues as to how these interactions work. Improving the quality and long-term security of water supplies, enhancing agricultural productivity, and planning for the avoidance or mitigation of environmental hazards are all of high priority for human societies, and they all require a good understanding of past variability, human responses, and human–environment interactions.

13 Paleosols

Gregory Retallack

Abstract

Soils are known to be products of environmental factors such as climate, vegetation, topographic setting, parent material, and time for formation so that paleosols, or fossil soils, can potentially reveal changing environments of the past. Evidence from paleosols for past climate and vegetation in East Africa does not support traditional narratives of human evolution during a single transition from primeval forest to dry climate and open grassland. Instead, paleosols indicate climatic oscillations between wet and dry, and alternating expansion of woodland and grassland, since at least 18 Ma (million years ago). Acquisition of dry grassland adaptations such as thick enamel by 18 Ma, adducted hallux by 14 Ma, and cursorial legs by 1.8 Ma, alternated with woodland adaptations such as short stiff back by 16 Ma, erect stance by 6 Ma, and flat face by 3.5 Ma. Our ancestors survived profoundly changing climate and vegetation, with some adaptations lasting only to the next environmental shift, but others proving to be of lasting value.

13.1 Introduction

Our species, and its ancestors of millions of years ago, evolved on the soils of Africa (Darwin 1872; Fleagle 1998). Many of those soils have been eroded or altered beyond recognition by deep burial, but many paleosols are buried within floodplain, volcanic, lacustrine, alluvial plain, and cave deposits of Africa (Retallack 2001a). These paleosols provide much of the colorful banding and mottling seen in East African badlands and dongas, including many fossil hominoid localities (Figure 13.1). Many fossils of human ancestors come from paleosols (Retallack et al. 1995, 2002; Radosevich et al. 1997; Wynn 2004a, b), which are also records of past environments of our evolutionary antecedents (Figure 13.1). Modern soils are known to be products of environmental factors such as climate, vegetation, parent materials, topographic setting, and time for formation (Jenny 1941). These formative factors can be interpreted from fossiliferous paleosols to provide hitherto unavailable details of the habitats of fossil apes and humans.
The vegetation of fossil ape and human sites is central to long-standing theories for the evolution of upright stance. “The hands and arms could hardly have become perfect enough to have manufactured weapons, or to have hurled stones and spears with a true aim, ‘... so long as they were especially fitted to climbing trees’” (Darwin 1872). Other ideas are that grasslands selected for upright stance because of the need to be vigilant against predators (Dart 1926), to manipulate small seeds (Jolly 1970), to minimize exposure to the sun (Wheeler 1984), or to cover long distances with less energy by walking (Rodman and McHenry 1980) or running (Bramble and Lieberman 2004). Wooded grasslands and open woodlands are also plausible sites for evolution of upright stance from squat feeding on the ground (Kingdon 2003) or moving between scattered fruiting bushes (Sanford 2003). Alternatively, upright stance may have evolved in forests because it allowed erect-back climbing (Tuttle 1981), hands free to care for premature infants (Lovejoy 1981), phallic display to females (Tanner 1981), or intimidation displays to rivals (Jablonski and Chaplin 1993).
Paleosols are relevant to these questions because the fine root traces and crumb structure of grassland soils are distinct from the thick clayey subsurface horizons of both woodland and forest soils (Jenny 1941). Woodland and forest soils differ markedly in their clay minerals and chemical composition (Retallack 1997). Even the aquatic theory of human origins (Morgan 1982) can be evaluated from paleosols because mangal, littoral, lake margin, and streamside paleosols are distinguished by virtue of relict bedding and common burrows of crabs and clams (Retallack 2001).

Paleoclimate also is of interest as a selective pressure on hominoid evolution through drought and other hardships. Paleoclimate was also a primary control of past vegetation in which hominoids found food and shelter. Paleoclimatic shifts to drier climate and more open grassy vegetation have been held responsible for major evolutionary innovations in hominoids and bovids (Vrba 1999), as have changes in degree of climatic variability (Potts 1996). Soils of dry climate have calcareous nodules at a shallower depth than soils of humid climate (Retallack 2004) and also are less leached of cationic nutrients (Ca$^{2+}$, Mg$^{2+}$, K$^+$, Na$^+$) than humid-climate soils (Sheldon et al. 2002). Paleosols can thus provide paleoclimatic records at the very sites of early human ancestors rather than inferred from remote records of deep-sea cores (de Menocal 2004).

This review emphasizes climate and vegetation, but other soil forming factors of parent material, topographic position, and duration of soil formation can also be inferred from paleosols. Highly calcareous and saline carbonatite volcanics are an unusual parent material of many African hominid sites (Retallack 1991a), fortunate because of their remarkable preservative effects for fossil bones, seeds, and insects (Retallack et al. 1995). Many East African paleosols preserve a record of well-drained fluvial terraces, infrequently flooded, and some volcanic apron paleosols represent foothills environments (Retallack 1991a), thus revealing environments beyond the usual lowland constraints of sedimentary environments. Degree of soil development can also be used to infer duration of paleosol formation and rates of sediment accumulation, with implications for the geochronology of ape and human ancestor sites (Retallack et al. 1995, 2002).

### 13.2 Recognition of paleosols

Paleosols are often distinctive and striking bands of red clay (Bt horizon), calcareous nodules (Bk horizon), or coal (O horizon) in sedimentary and volcanic sequences (Figure 13.2). Three general classes of observations are especially helpful in paleosol recognition: root traces, soil horizons, and soil texture (Retallack 1997).
Kenyan Miocene paleosols have been given field names using local Luo and Turkana languages. These pedotypes are objective field mapping units for paleosols: their interpretation and classification requires laboratory study.

![Figure 13.2](image-url)
Root traces are the most diagnostic evidence of paleosols and sometimes are obvious because cemented and erosion-resistant (Kabisa pedotype of Figure 13.2). Difficulties arise in recognition of root traces because they are often replaced by other minerals and ramify in three dimensions in such a way that one rock face reveals little of the overall pattern. Few fossil roots are carbonaceous or reveal histological structures like fossil wood (Retallack 1997). The original root has commonly rotted out, and the hole it occupied is filled with claystone or siltstone, or encrusted with iron oxide or calcium carbonate. Drab haloed root traces are very distinct, green gray mottles, in reddish paleosol matrix, formed during early burial chemical reduction by microbes fueled by consumption of root organic matter (Retallack 1991b). In all these cases, root traces are truncated at the surface of the paleosol, and branch and taper downward. These features distinguish root traces from most kinds of burrows in soils, although the relationship between burrows and roots can be complex. Roots may preferentially follow soft fill of burrows rather than hard soil matrix, and burrows may congregate around roots on which the burrowing animals fed (Retallack 1991a).

Soil horizons develop through thousands of years whereas sedimentary beds are deposited in days. Unlike sedimentary beds, which have sharp bottoms and usually sharp tops as well, paleosols have a sharp top, representing the ancient land surface, but gradational lower contacts (Retallack 2001a). Sedimentary beds also include a variety of sedimentary structures, such as lamination, cross bedding, and ripple marks (as in Tek pedotype of Figure 13.2), whereas soil horizons develop with obliteration of these original features (Tut pedotype of Figure 13.2). Similarly, soil formation progressively destroys the original crystalline structure of volcanic or granitic parent materials (Retallack 1991a). In dry climate soils (Aridisols), primary sedimentary or volcanic structures are obscured at first by filaments and soft, small carbonate masses, then large, hard, carbonate nodules (calcic or Bk horizon of Chogo pedotype in Figure 13.2), and finally thick carbonate layers (petrocalcic or K horizon of Soil Survey Staff 2000). In sod-grassland soils (Mollisols), primary lamination and crystalline structure is broken up by fine roots and replaced by dark, fecal pellets of earthworms to create a crumb-textured, organic surface horizon (mollic epipedon of Dite, Chogo, Yom, and Onuria pedotypes of Figure 13.2). A variety of other kinds of soil horizons are recognized and important to soil classification (Retallack 1997, 2001a; Soil Survey Staff 2000).

Soil structure also develops within soil horizons and is very distinct from sedimentary bedding and igneous crystalline texture. The fundamental elements of soil structure are modified cracks and other surfaces (cutans), and the clods they define (peds). Cutans include clay skins (argillans) lining cracks in the soil.
and rusty weathering rinds (sesquans) around clods and pebbles in soil (Retallack 2001a). Peds have a variety of shapes: lenticular in swelling-clay soils (Vertisols: Aberegaiya pedotype of Figure 13.2), blocky subangular in fertile forest soils (Alfisols: Tut pedotype of Figure 13.2), and crumb shaped (small and ellipsoidal) in grassland soils (Mollisols: Dite, Chogo, Yom, and Onuria pedotypes of Figure 13.2). Although cracks and other voids are not preserved in paleosols due to compaction by overburden, peds, and cutans are common and conspicuous (Retallack 1991a). Other soil structures less diagnostic of soils include concretions, nodules, and crystals (Retallack 2001a).

### 13.3 Methods for the study of paleosols

Just as soil individuals (pedons) are studied as soil columns in soil pits, paleosols are studied in columnar stratigraphic sections of the sort also used in sedimentology and stratigraphy (Figure 13.3). Grain size is emphasized because it is important to soil formation, as weathering transforms sand and silt grains to clay. A graphical representation of grain size profiles conveys important information on the abruptness of horizon transitions. Color from a Munsell chart should also be represented, as redness denotes the degree of chemical oxidation and drainage of soils and paleosols. Calcareousness determined by relative effervescence with dilute hydrochloric acid also is important as a guide to chemical leaching and soil nutrient status (Retallack 1997).

Laboratory studies of paleosols do not employ all the same techniques used in soil science because some important soil measures, such as base saturation, are altered upon burial of soils (Retallack 1991b). Petrographic thin sections are especially useful for revealing soil microfabrics, and the point counting of thin sections furnishes estimates of changes in grain size and mineral composition of paleosols. For example, increased subsurface clayeyness can be used to recognize diagnostic horizons (argillic horizon) for forest soils (Alfisols and Ultisols), whereas traces of nutrient-rich minerals, such as calcite and feldspar, distinguish fertile forest soils (Alfisols) from infertile forest soils (Ultisols: Retallack 1997).

Chemical analyses also are useful in characterizing and classifying paleosols, especially molar ratios designed to gauge the progress of common soil-forming chemical reactions. The hydrolysis reaction common in silicate weathering leaches cationic bases ($\text{Ca}^{2+}$, $\text{Mg}^{2+}$, $\text{K}^+$, $\text{Na}^+$) from host minerals, such as feldspar, to create clay (Al rich) and is thus indicated by high ratios of alumina/bases. An alumina/base ratio higher than 2 is a good proxy for the transition from fertile forest soils (Alfisols) to infertile forest soils (Ultisols). Soda/potash molar ratios in excess of 1 indicate unusually salty soils. Ferrous/ferric molar ratios in
Figure 13.3
Petrographic and chemical data for the Tek paleosol from the 18 Ma Hiwegi Formation of Rusinga Island, Kenya [data from Retallack et al. (1995)]
excess of 1 indicate well-drained soils (Retallack 1997). By these criteria, the petrographic and chemical data on the 18 Ma Tek paleosol from Rusinga Island Kenya (Figure 13.3) indicate a fertile Inceptisol that was nonsaline and well-drained. These data allow identification of analogous modern soils (Retallack et al. 1995) and refine understanding of the ancient landscape and its ecosystem (Figure 13.4).

Figure 13.4
Reconstruction of Tek paleosol from the 18 Ma Hiwega Formation of Rusinga Island, Kenya [data from Retallack et al. (1995)]
Carbon isotopic compositions of paleosol carbonate were at first thought to be useful indicators of grasslands because most tropical grasses have a C$_4$ photosynthetic pathway which creates isotopically heavy carbon (Cerling 1992). The most prominent failure of this technique was application to the Middle Miocene (14.4 Ma) locality of Fort Ternan, with paleosol carbonate isotopically like rain forest (Cerling et al. 1997a), but fossil soils, grasses, trees, and antelope like those of a mosaic of wooded grassland and grassy woodland (Retallack 1991a, 1992; Koch 1998; Turner and Antón 2004). Subsequently it was found that even tropical grasses used the C$_3$ photosynthetic pathway until about 7 Ma or younger (Cerling et al. 1997b; Fox and Koch 2003). The quality of graze (C$_3$ more nutritious than C$_4$) can be assessed by isotopic studies of teeth and paleosols, but the question of grass or shrub diet is better assessed from mammalian tooth microwear, hypsodonty, and cursoriality (MacFadden 2000). The advent of C$_4$ grasses within tropical grasslands is most likely related to declining Late Miocene atmospheric CO$_2$ content (Cerling et al. 1997a). Another failure of carbon isotopes to indicate past vegetation is Sike’s (1994) forest interpretation of the paleosol at Olduvai fossil locality FLK yielding *Australopithecus boisei*. This paleosol with relict bedding, zeolites, little clay, and shallow carbonate is unlike forest soils, and probably supported salt-tolerant, lake-margin shrubs (Retallack 2001a), which have a similar C$_3$ isotopic value to forest (Sikes 1994). Isotopic values of carbon and oxygen in paleosols and animals are controlled by so many factors that biotic and pedogenic constraints are needed (Koch 1998). Carbon isotopic studies of paleosols are now more useful for assessing atmospheric CO$_2$ from carbonate and organic isotopic offsets (Ekart et al. 1999) and soil productivity from isotopic depth functions (Yapp and Poths 1994). Carbon isotopic depth profiles of paleosols also provide new insights into carbon cycling within different kinds of ancient ecosystems. Grassland paleosols (Chogo and Onuria pedotype of Figure 13.5) show more effective humification at the surface (higher $\delta^{13}$C values) than woodland soils (Tut of Figure 13.5), and swelling-clay paleosols have flat carbon isotopic profiles due to soil mixing (Chido of Figure 13.5). Preservation of such carbon-cycling signatures known from modern soils within different pedotypes gives additional evidence for paleosol classification and interpretation (Bestland and Krull 1999).

### 13.4 Paleosols as proxies of paleoprecipitation

Climatic zonation of soils was a key element in the Russian origins of soil science (Jenny 1941), and a variety of relationships between particular soil features and climatic variables can be applied to East African paleosols in order to reconstruct...
paleoclimate. For example, depth to carbonate horizon \((D\text{ in cm})\) is related to mean annual precipitation \((P\text{ in mm})\) by formula (1) below (from Retallack 2005). This depth can be corrected for compaction due to overlying sediment using geological estimates of overburden and standard formulae (Sheldon and Retallack 2001). Also related to mean annual precipitation \((P)\) is nutrient base content \((C = \frac{Al_2O_3}{Al_2O_3 + CaO + MgO + Na_2O})\) in mol) of soil Bt horizons by formula (2) below (Sheldon et al. 2002).

\[
P = 137.24 + 6.45D - 0.013D^2 \quad R^2 = 0.52, \text{ S.E. } = \pm 147 \text{ mm} \quad (1)
\]

\[
P = 221.12 \cdot e^{0.197C} \quad R^2 = 0.72, \text{ S.E. } = \pm 182 \text{ mm} \quad (2)
\]

Chemical weathering also alters the mineral content of soils, especially their clay minerals, which begin as smectites and then lose cationic bases with further chemical weathering to become kaolinite (Retallack 2001). This indication of paleoprecipitation works best with noncalcareous soils, which are found in climates receiving more than 1,000-mm mean annual precipitation (Retallack 2004). In East Africa today, smectite is dominant in soils receiving less than 1,200-mm mean annual precipitation, and kaolinite dominant in wetter climates.
Thus noncalcareous, smectitic soils define a limited paleoclimatic window of 1,000–1,200-mm mean annual precipitation.

My new compilation of Kenyan paleoprecipitation over the past 20 million years (Figure 13.6b) includes previously published data on African depth to Bk (Wynn 2001, 2004a, b; Wynn and Retallack 2002; Retallack 2001b; Retallack et al. 2002), and paleosol chemical (Retallack et al. 1995, 2002; Thackray 1989; Bestland 1990; Retallack 1991a; Wynn and Retallack 2002) and clay mineral composition (Retallack 1991a, Behrensmeyer et al. 2002), as well as published inferences from size and shape of fossil leaves (Jacobs 2002). This compilation is limited to data from around Lake Victoria for the early-middle Miocene, the Tugen Hills for the mid-late Miocene and the Turkana Basin for the Miocene to Quaternary. The geological time scale is from radiometric dating of these various fossil primate sites (Deino et al. 1990; Retallack 1991a, Jacobs and Deino 1996; Behrensmeyer et al. 2002; Hill et al. 2002).

These new data reveal not just one Neogene aridification event at about 7 Ma, as has long been implied by the “Tertiary pluvial hypothesis” (Leakey 1952), the “Miocene lake hypothesis” (Kent 1944), the “Miocene rain forest hypothesis” (Andrews and Van Couvering 1975; Andrews 1996), and the “Late Miocene grassland hypothesis” (Cerling 1992; Cerling et al. 1997a, b). These theories had already been discredited by discovery of Miocene desert dunes, shrubland snails, alkaline lakes, open-country grasses, grazing mammals, and grassland paleosols in East Africa (Pickford 1986a, 2002a; Retallack et al. 1990, 2002).

Instead the data (Figure 13.6) reveal a Neogene paleoclimatic roller coaster of at least nine dry spells with intervening wet periods, of which humidity spikes at 16 and 13 Ma were the wettest of the last 20 million years. This new paleoprecipitation curve is similar to paleotemperature variations for Africa inferred from north–south oscillation through time of Ethiopian and Palearctic biogeographic realms (Pickford 2002a). These new data are also similar to foraminiferal oxygen isotope curves from the deep sea (Zachos et al. 2001), commonly used as a basis for evaluating human evolution in Africa (de Menocal 2004), but the match is not precise (Figure 13.6b and c). A general trend of extreme and volatile middle Miocene values, but subdued late Miocene to Quaternary values, is evident from both isotopic and paleosol data. The paleosol record reveals much greater variation in rainfall than would be inferred from carbon isotopic values of marine foraminifera, which are damped by global oceanic mixing with time lags of several thousand years. More profound damping is seen in oxygen isotopic values of marine foraminifera, which show a long-term increase unlike local rainfall and foraminiferal carbon records. This increase is plotted on reversed axes in Figure 13.6d because it has been interpreted as a long-term temperature
Figure 13.6
A 20 million year record of vegetation (a) and paleoprecipitation (b) from Kenya, compared with carbon (c) and oxygen (d) isotopic composition of marine foraminifera. Paleoprecipitation data from paleosols (b) is from depth to carbonate (open ellipses), clay mineral (diamonds), and chemical composition (squares) after Retallack (1991a), Retallack et al. (1995, 2002), Wynn (2001, 2004a, b), Wynn and Retallack (2001). Paleobotanical estimates from Jacobs (2002) and Jacobs and Deino (1996). Modern vegetation precipitation limits are from Anhuf et al. (1999).
decline (Zachos et al. 2001), but part of this long-term trend is due not just to temperature but to water recycling with plate tectonics (Veizer et al. 2001). The global oxygen isotope record also shows an increase after 3 Ma due to continental icecap sequestration of isotopically light oxygen, in addition to temperature effects (Zachos et al. 2001). Despite these problems, the East African paleosol record and global isotopic records present a very different concept of climatic variation experienced by our distant ancestors than the past idea of a seminal Late Miocene climatic event. Instead of a single origin of humanity at a turning point of environmental change, the new record implies rather that our lineage responded to a gauntlet of changing conditions with a variety of adaptations (Table 13.1), as discussed later.

13.5 Paleosols as trace fossils of ecosystems

*Australopithecus afarensis* is known from body fossils, such as the partial skeleton “Lucy” (Johanson et al. 1982), as well as from trace fossils, such as the footprints of Laetoli (Leakey and Harris 1987). The soils of *A. afarensis* also are known, especially at the “first family” site near Hadar, Ethiopia (Radosevich et al. 1992). Here a troop of at least 13 individuals, young and old, died, rotted, and were
partially disarticulated, before being interred in flood deposits on a crumb-structured soil of grassy streamside woodland (Figure 13.7). The paleosol is not only a matrix to the bones but a trace fossil of their ecosystem. Furthermore, paleosols by definition are in the very place they formed, not redeposited. Unlike the skeleton of “Lucy” found in the sandstone of a former river channel (Johanson et al. 1982), and thus transported some distance from its natural habitat, the first family was found where it died and had lived (Radosevich et al. 1992). Thus, paleosols give a finer resolution of primate paleoenvironments in time (Figure 13.6) as well as space (Figure 13.7).

The various paleosols containing Miocene ape fossils in southwest Kenya can also be used to constrain their habitats (Figure 13.8). The fragmentary and weathered nature of most of these fossils is evidence that they accumulated through natural processes of death and decay on the paleosols in which they are found (Pickford 1986a). The great diversity of fossil apes in this region (Gommery et al. 2002; Harrison 2002; Ward and Duren 2002) is in contrast to the low diversity of great apes today (Fleagle 1998), leading to the idea that Miocene apes, defined from apelike dentition, were ecologically more like both
Figure 13.8
Paleosols of Miocene apes from southwestern Kenya [data from Retallack (1991a) with taxonomy after Harrison (2002), Retallack et al. (2002), Ward and Duren (2002)]
apes and monkeys today (Andrews 1996). Analysis of their occurrence in paleosols shows that there was some ecological separation of different species to different soil types, but still high diversity within a soil type (Figure 13.8). In the 20 Ma sites of Koru and Songhor, for example, one taxon (Ugandapithecus) shows little habitat specificity through a variety of tropical dry forest habitats, but small taxa (Kalepithecus, Mabokopithecus) are in upland soils and larger taxa (Proconsul, Rangwapithecus, Dendropithecus, Nyanzapithecus) remained in lowland forests closer to water. One paleosol type (Kiewo pedotype) has as many as six taxa: three likely suspensory feeders (Limnopithecus, Dendropithecus, Ugandapithecus from small to large) and three likely overbranch feeders (Nyanzapithecus, Proconsul, Rangwapithecus, from small to large). The contrasting sizes and other differences between these taxa suggest niche partitioning of forest canopy tiers.

Diverse sympatric catarrhine communities persisted into the dry woodland landscapes of Rusinga Island at 17.8 Ma, when paleosols with the crumb peds and iron–manganese nodules of dambo grasslands (Yom pedotype) appear, but are rare and barren of primate fossils (Retallack et al. 1995). Other evidence for grasslands of about the same age are abundant bunch grasses at the Ugandan fossil site of Bukwa (Pickford 2002b). Yom paleosols of dambo grassland are much more common by 14.7 Ma on Maboko Island (Retallack et al. 2002), where they contain abundant vervet-like monkeys (Victoriapithecus: note change of scale for this exceptional collection in Figure 13.8). These seasonally inundated grasslands of dry climates were not encouraging to fossil apes, which were more common in riparian woodlands (Nyanzapithecus, Limnopithecus, Mabokopithecus and Simiolus of Dhero paleosols). More wide ranging was Kenyapithecus, found in both riparian woodland (Dhero) and nyika shrubland (Ratong), which it exploited more effectively than other apes because of its thick enameled, large molars useful for tough foods (Martin 1985) and its macaque-like limbs and feet ( McCrossin et al. 1998). A similar pattern of wide ranging Kenyapithecus and forest-dependent other apes (Oreopithecus, Simiolus, Proconsul) persisted in grassland mosaics of Fort Ternan and Kapsibor at 14.4 Ma, when well-drained short-grass, wooded grassland was widespread. The appearance of grasslands so encouraging for victoriapithecine ancestors of vervets and colobines, was not so encouraging to apes, which remained rare components of the fossil fauna.

Reconstruction of rainfall from paleosols implies also vegetation belts (Figure 13.6a), by comparison with Holocene climatic ranges of plant formations (Anhuf et al. 1999). There was rainforest in central Africa during the past 20 million years as indicated by rare finds of fossil plants (Bancroft 1932, 1933), but evidence of rain forest has not yet been found in the East African areas of hominoid fossils (Retallack 1991a, Jacobs 2002). These interpretations (Figure 13.6a) are well in accord with indications of vegetation from paleosol classification, profile
form and root traces (Retallack 1991a), as evidence that the climatic range of
most vegetation types did not change over the past 20 million years.

An exception is the evolution of grasslands, which expanded their climatic
range to displace extinct kinds of woodlands (Figures 13.6 and 13.9). There is
not yet any East African evidence of grasslands before 17.8 Ma, when crumb-
textured, brown, simple (A-Bk) profiles of dambo were rare at Rusinga Island
(Retallack et al. 1995) and bunchgrasses grew luxuriantly at Bukwa (Pickford
2002b). Well-drained, short-grass, sod-grasslands were widespread by 14.4 Ma
(Retallack 1991a, Retallack et al. 2002) and well-drained, tall-grass, sod-grasslands
expanded their climatic range considerably by 7 Ma (Wynn 2004a, b). Grasslands
were a newly coevolved ecosystem of the Cenozoic, with grasses uniquely suited
to grazing by virtue of their intercalary meristems, modular growth, basal tiller-
ing, and sod formation, and grazers uniquely suited to coarse grassy fodder by
virtue of their wide muzzles, hypsodont teeth, and hard hooves (Retallack 2001a).
A world without grasslands was transformed over some 20 million years to a Plio-
Pleistocene world with grassland covering at least a quarter of the land surface.
Holocene humans spread grassy agroecosystems to almost all parts of the world
(Retallack 2001a). Neogene expansion of grasslands within the paleoclimatic belt
roughly defined by the 300–750 mm per annum isohyet enabled grasslands to
capture the planetary modal rainfall belt and most fertile soils, with consequences
for global change including a significant contribution to global cooling (Retallack
2001b).

Before the expansion of the grasslands, an extinct woody vegetation occupied
their climatic range (Figure 13.6). I call these extinct dry woodlands pori
(Table 13.2), from a Hadza word for bush (Woodburn 1968). A good example
of a pori ecosystem is the Tek paleosol of Rusinga Island (Figures 13.3
and 13.4), which has yielded fossil primates and other mammals, snails, and plants
(Pickford 1995; Retallack et al. 1995). Other examples of pori ecosystems include
Tut, Choka, and Kwar pedotypes of Songhor and Koru dated at 20 Ma (Retallack
1991a). From the soil perspective, these paleosols have no clear modern analog
because they are red and clayey, with large root traces and blocky structure like
woodland soils, yet have shallow calcareous horizons like those found in modern
African semiarid to subhumid grassland soils. Modern African soils with such
shallow carbonate have very different crumb structure, fine root traces, and dark
brown organic-rich surface horizons from abundant grasses.

From the paleoanthropological perspective, these ancient communities have
no modern analogs because they have so many fossil hominoids, as many as six
species in the Kwar pedotype (Figure 13.8). No community has so many species
of hominoids today. Nor do modern hominoids live in such dry climates. Mt. Assirik in Senegal with 956 (854–1224) mm mean annual precipitation is
the driest climate with chimpanzees (Kappelman 1993), although Kingdon (2003) gives anecdotes of chimpanzees in wooded grassland. It is now clear that Miocene apes filled a variety of niches like those today filled by vervets, baboons, and colobines as well as apes (Retallack et al. 2002). Pori ecosystems such as the Kwar paleosol at Koru (20 Ma) also show peculiar associations of other mammals, including a mix of dry climate taxa, such as mole rats (*Bathyergoides*), with wet climate taxa such as flying squirrels (*Paranomalous*), giant elephant shrews (*Miorynchocyon clarki*), tenrecs (*Protenrec tricuspis*), golden moles (*Prochrysochloris miocaenicus*), and chevrotains (*Doratherium songhorense*; Retallack 1991a). Similarly the Tut and Choka paleosols at Songhor (20 Ma) and Tek paleosols on Rusinga Island (17.8 Ma) have wet climate flying squirrels and tenrecs as well as dry climate mole rats and spring hares (Retallack 1991a; Retallack et al. 1995). These nonanalog combinations of fossil mammals can be explained by a theory of evolutionary replacement of pori with grassland within semiarid to subhumid regions. Before the advent of grasslands, woody vegetation became smaller in stature and biomass from wet to dry regions. This continuum was disrupted as grasslands evolved to usurp the climatic range of pori woodland. Grasslands expanded their range to create a biogeographic divide between Nyika shrubland and miombo woodland (Figure 13.9).

Fossil primates of East Africa not only coped with changing mixes of animals but with changing climate and vegetation (Figure 13.6). Wynn (2004b) has introduced the concept of evolutionary entropy to explain effects of climate and vegetation change on hominoid diversity. Climatically dry episodes encouraged grassland mosaic environments with a more varied landscape of open grassland and local woodland, and thus greater landscape disorder or negentropy. Wet episodes of forest vegetation presented more uniform landscapes of higher entropy. My compilation of hominoid diversity, originations, and extinctions (Table 13.1, Figure 13.10) supports the view that dry episodes correspond with diverse primates, whereas wet episodes lead to extinctions, particularly of specialized arid-adapted taxa. The concept of ecosystem entropy in hominoid evolution is similar in some respects to Vrba’s (1999) “turnover pulse hypothesis,” but ecosystem entropy presents diffuse and long-term selection pressures, rather than episodic crises or “turnover pulses.” Recent compilations of mammalian

Tut paleosol Songhor 20 Ma
data from the Turkana region do not show such crises (Bobe et al. 2002), revealing instead an oscillating diversity compatible with less synchronized selection by ecosystem entropy.

A major caveat for such theories is the generally inferior fossil record of climatic wet phases because their soils and sediments are noncalcareous and so not favorable to the preservation of bone (Retallack 1998). We still have no primate fossil record from paleoclimatic wet phases of the early Miocene, but there are discoveries of wet climate human ancestors from 13 Ma (Hill et al. 2002), 6 Ma (Brunet et al. 2002; Galik et al. 2004) and 4–3 Ma (Carroll 2003). The soil-taphonomic bias against wet climate fossils makes the search difficult, not impossible (Peterhans 1993).

Each fluctuation in climate and vegetation presented new crises and opportunities to primates. My own correlation of climatic events with critical adaptations (Table 13.1) is only an outline of a new research agenda, to be fleshed out with further studies of the critical intervals. The late Miocene paleosols and primate fossils of the Tugen Hills, for example, remain very poorly known compared with those of the Lake Victoria and Turkana basins. Nevertheless, there are general themes apparent from this compilation. We did not evolve from apes in one seminal event, but by a protracted process of growth and pruning of our evolutionary tree. Some specialized features such as procumbent incisors at 18 Ma evolved in dry grassy woodlands, but did not survive succeeding forest expansions (McCrossin and Benefit 1997). Some specialized features such as long arms

by 20 Ma for suspensory locomotion in forests did not persist through succeeding grassland expansions (Harrison 2002). Other forest adaptations such as a short-stiff back by 16 Ma (Pickford et al. 1999), erect stance by 6 Ma (Senut et al. 2001; Galik et al. 2004), and flat face by 3.5 Ma (Leakey et al. 2001) proved advantageous in the long term, just as did grassland adaptations, such as thick enamel by 18 Ma (Martin 1985; McCrossin and Benefit 1997), adducted hallux by 14.7 Ma (McCrossin et al. 1998), and long legs for endurance running by 1.8 Ma (Bramble and Lieberman 2004). Although each of these ideas could be debated individually, the general concept of human evolution as a generalist path through a gauntlet of environmental challenges (Potts 1996) is increasingly supported by a burgeoning fossil record (Carroll 2003). There will always be a need for dating and finding more human ancestor fossils, but paleosols now provide new evidence of evolutionary selection pressures with high temporal and spatial resolution.

Past hypotheses of a Miocene pluvial, lake and rain forest (Kent 1944; Leakey 1952; Andrews and Van Couvering 1976; Andrews 1996) and late Miocene grassland (Cerling 1992; Cerling et al. 1997a, b) find, as already reviewed, a counterpart in long-standing theories linking late Miocene evolution of human upright stance or large brains with hunting prowess (Darwin 1872), vigilance against predators (Dart 1926), manipulation of small seeds (Jolly 1970), minimization of sun exposure (Wheeler 1984), long-distance walking (Rodman and
McHenry 1980) or running (Bramble and Lieberman 2004), squat feeding on the ground (Kingdon 2003), or moving between scattered fruiting bushes (Sanford 2003). Forest explanations of upright stance allowing erect-back climbing (Tuttle 1974), hands free to care for premature infants (Lovejoy 1981), phallic display to females (Tanner 1981), or intimidation displays to rivals (Jablonski and Chaplin 1993) move the event back into the “Miocene rain forest” (of Andrews and Van Couvering 1975; Andrews 1996), for which there is little evidence at hominoid sites in East Africa (Figure 13.6a). All these views can be reassessed in light of the improved record of East African paleosols, which suggests that there were many alternating habitats in East Africa, not just one seminal environmental shift. Darwin’s (1872) idea that erect stance was linked to tool use and brain expansion has been out of favor since the discovery of “Lucy,” when it became clear that erect stance preceded tool use and brain expansion by millions of years (Johanson et al. 1982). Erect stance now appears to have occurred in wooded habitats by 6 Ma (Pickford and Senut 2001; Vignaud et al. 2002), perhaps selected by the use of hands in nest provisioning (Lovejoy 1981). We are a mosaic of a complex evolutionary history and no longer need settle for simple or single allegories of human evolution.

13.6 Conclusions

There is a copious and informative fossil record of soils at most of the fossil ape and human ancestor sites in Africa, and study of these paleosols is now giving important insights into the long evolutionary career of our ancestors. The primate evolutionary radiation of the Neogene has been a long saga of changing habitats and adaptations. The fossil record of soils now allows us to address its complexity on a scale appropriate to primate home ranges and to recognize nonanalog habitats of the past. Our ancestors have run an evolutionary gauntlet of changing climate and vegetation that have spawned many evolutionary innovations, some of them lasting only to the next shift in climate and vegetation, but others of them proven to be of lasting value.

Acknowledgments

I thank my companions of Kenyan expeditions Erick Bestland, Glenn Thackray, Dan Dugas, Jonathan Wynn, Doug Ekart and Hellen Vallianatos. Brenda Benefit, Monte McCrossin and Stephen Gitau helped with transport and accommodation to Maboko, and Meave Leakey was equally hospitable at Kanapoi. Richard and Meave Leakey, Martin Pickford and Christine Kabuye were especially helpful with access to the Kenyan National Museums collections.

14 Quaternary Deposits and Paleosites

Klaus-Dieter Jäger

Abstract

Due to the mineral content of bones and teeth, the majority of fossil hominid remains are represented by these tissues; soft parts of the human body are preserved only very rarely. Whether or not fossils are well preserved depends on the nature of the deposits in which they are enclosed. Numerous methods are now available for chronometric dating of hominid fossils, though none of them is applicable in all situations. However, it is still necessary to situate each hominid fossil within the larger stratigraphic framework. Hominid evolution began well over 4 million years ago, and covered the final part of the Neogene (Upper Tertiary). As a result, ongoing international discussions of stratigraphic boundaries over this span are also significant for the assessment of the hominid evolution. In addition to providing stratigraphic information paleoanthropological sites provide not only insights into the environmental backgrounds of the fossils they yield, but in later periods commonly also into the cultural evolution of mankind and its relatives.

The preservation and suitability for investigation of physical remains left behind by hominids from past centuries or millennia or from periods still longer ago depends mainly on two circumstances:

1. Nature of the fossil remains.
2. Quality and nature of the fossiliferous deposits, as a rule sediments of Pliocene, Pleistocene, or Holocene age.

14.1 Characteristics of fossil remains

Among the preserved remains, hard components from the skeleton are more commonly found, i.e., bones and teeth. Soft parts are more rare.

The preservation of bones and teeth is determined by the content of calcium carbonate in the fossiliferous deposits. In the case of soft parts, their accessibility
to decomposition is determined by the contemporaneous availability of water and atmospheric oxygen.

If one of these two factors is kept to a minimum, the decomposition processes are reduced or stopped.

The access of atmospheric oxygen is reduced in the case of subaquatic sedimentation or sediment conservation (e.g., in inland waters) or in the case of deposits lying below the groundwater table (e.g., peat in boggy terrain). Such conditions characterize the sites of bog bodies. On the other hand, desert areas with minimized water supply provide plenty of atmospheric oxygen access, but the decomposition of organic matter is impeded by the lack of water. In these areas, an essential precondition for a lot of chemical processes is missing. Consequently, under such conditions the decomposition of organic matter is reduced, but frequently the prerequisites for mummification are realized.

More often the preservation of fossil remains is restricted to hard components only. Independent of the local presence of water and atmospheric oxygen, the preservability of bones and teeth is determined by their preservable quality consisting of apatite. This component is characterized by the formula:

\[ 3 \text{Ca}_3(\text{PO}_4)_2 \times \text{CaF}_2. \]

Fossils in limeless deposits are protected from progressive corrosion and destruction since the superficial precipitation is not pure water.

As it passes through the atmosphere prior to precipitation, the rainwater is contaminated by carbon dioxide (CO₂). Consequently, a weak carbonic acid (H₂CO₃) touches every surface, and the lime content in the soil comes in contact with the acid according to the following formula:

\[ \text{CaCO}_3 + \text{H}_2\text{O} + \text{CO}_2 \rightarrow \text{Ca(HCO}_3\text{)}_2 \]

If the subsoil contains a lot of calcium carbonate or a diffuse lime distribution, the first stages of decalcification are concentrated on the lime content of fossiliferous deposits and buried soils, and for a while bones and teeth remain protected against corrosion and dissolution. On the other hand, in limeless deposits, such fossils are the only objects vulnerable to corrosive processes.

### 14.2 Characteristics of fossiliferous deposits

Consequently, bones and teeth in limy deposits are also exposed to corrosive destruction but to a lesser degree. In the case of limy deposits, it is more or less insignificant whether the fossiliferous sediments are loose ones with high porosity (such as sands or loess) or solid rocks (like travertine). Both provide sufficient and favorable conditions for the preservation of human skeletal remains, and this is why finds and sites of paleoanthropological significance are mainly connected
with such deposits. In detail, such conditions are shared mainly by the following sediment types:

1. Fresh-water lime deposits (calcareous deposits from inland waters, as a rule consisting of >90% CaCO₃, frequently modified by diagenesis and especially to be found in travertines)
2. Loess (dust deposits of eolian origin, characterized by lime content, as a rule between 15% and 30% CaCO₃) with dust layers, intercalated by buried soils, frequently with calcareous (and also with decalcified) humus horizons
3. Cave deposits, especially in karstified calcareous mountainous regions, where caves originated from subterranean drainage ways and were occupied by human entry and settlement after drying (which often happened as a result of moving of the original water way)
4. Calcareous debris, especially in mountainous regions, in open-air sites (lime content of the rock detritus being identical to that of the solid rock, perhaps less in the intermediate matter)
5. Calcareous fluvial and deltaic gravels and sands, however preferably containing displaced objects
6. Calcareous lacustrine and beach deposits, as a rule silty and clayey, sometimes laminated

In addition to these site types, those favoring the preservation of soft parts (as in the case of bog bodies) have to be considered, preferably in peat and limnic mud layers.

Moreover, tephras, i.e., pyroclastic deposits traced back to nearby volcanic eruptions—as in the case of Vesuvius during August 79 AD—enable the origination and preservation of human body imprints, which can be replenished by means of gypsum after detection. The method for such a procedure has been applied since the 1860s (since the year 1863 to be precise), first of all by the Italian archeologist Giuseppe Fiorelli who was the longstanding leader of the excavations at the ancient town Pompeii, which was covered by tephra and pumice on the occasion of the aforementioned Vesuvian eruption (Mau 1899). Exceptional finds are the brain endocasts as cited by way of example from the Eemian travertine at Gánovce in Slovakia (Vlček 1958).

**14.3 Possible methods for dating**

In many places, the geological preconditions for fossilized human remains are connected with sites of archeological discoveries proving previous human presence or even settlement. That is why frequently sites of significant paleoanthropological
finds are also highly important in terms of archeology. Not least, such in-site combinations facilitate the dating and the cultural-historical assignation of the respective paleoanthropological observations.

Moreover, the calcareous deposits mentioned above enable not only the preservation of human skeletal remains but also of comparable animal records. The paleozoological investigation of skeletal parts proving previous micro- and macromammals, as well as the determination and examination of fossil shells providing evidence of former mollusks or ostracods, contribute to biostratigraphical datings and paleoecological assessments. In particular, the investigation of mollusk remains is of special validity in Central and Western Europe, since there the precise species determination has been achieved, merely based on conchylia or even their fragments (Ložek 1955, 1964). Moreover, comparable methods of dating are also in preparation in other parts of Eurasia (actually Meng 2007).

However, the investigations of micromammals as well as of mollusks are not restricted to qualitative records. On the contrary, both categories of fossils provide the chance for quantitative analysis and statistical consolidation of the results. Moreover, the examinations permit the reconstruction of faunal assemblages as a basis for the paleoecological interpretation (Rousseau 1990). To such an extent, they contribute to the characterization of the natural environment surrounding previous mankind.

In travertines, frequently the paleozoological record is completed by leaf imprints and incrustations of various plant structures, contributing both to the dating of sites and to their paleoecological characterization.

In sequences of peat and limnic layers of mud or marl, the pollen analysis frequently offers an adequate method for dating. Altogether, paleobotany supports the dating of fossil human remains as well as the reconstruction of the paleoenvironment, especially in the case of travertine and bog sites.

However, all the mentioned paleontological and archeological procedures and observations contribute to relative chronology of sites, whereas the numerical or calendar chronology covering the whole time-span of fossil hominids requires another methodical approach. As a rule, the search for more or less precise dates, both in the geosciences and in archeological disciplines, is focused on so-called absolute chronology. However, already during the early 1980s, the paleontologist Jaeger (1981) claimed that this term is erroneous and—strictly speaking—inadmissible, since this term assumes the existence of absolute time, which is a physical and philosophical nonsense.

Independent of this terminological aspect, this calendar chronology of fossil hominids is mainly based on physical procedures, as summarized ao by Geyh (1980, 1983) and by Wagner (1995, 1998). The preferred methods are provided by
radiometry ($^{14}$C, Uranium series, $^{40}$K/$^{40}$Ar ao) and luminescence procedures (TL, OSL, IR-RF). In addition, the last 10–12 ka is within the reach of the botanical method of dendrochronology, but in practical terms this is restricted to wooden objects. Consequently, paleoanthropological finds can be dated by means of this method in close connection with preserved wood only. In Central Europe, the range of oak chronology provides “a high-resolution time scale for nearby the last 12000 years” (Spurk et al. 1998 p 1114).

However, the preservation of wood as a rule is subject to the same prerequisites as mentioned above with regard to soft parts of human bodies.

### 14.4 Geochronometrical perspective

The choice of applicable procedures suitable for numerical dating and calendar chronology of finds proving the presence of fossil men or early hominids is influenced to a high degree by the characteristics of the fossiliferous deposits. This means different composition of preserved material requires the application of different methods. Consequently, one must accept that there are differences regarding precision and range of dating. As a general rule, the tenet may be assumed that a short range is the inevitable consequence of precise high-time resolution and vice versa. Consequently and independent of the datable material, the older the finds are, the more imprecise is the numerical dating. This aspect is comparable with the optical perspective where the perceptibility of objects decreases with increasing distance. But this is only one aspect of geochronometric perspective.

Another aspect is related to the dated material. Fossil remains of men from historical times and in addition from the last millennia can frequently be dated directly, e.g., by using the radiocarbon method. Fossil remains from the Middle Pleistocene, i.e., finds with an age of a few or some hundreds of thousands of years, are not datable directly, but as a rule the fossiliferous deposits may be subjected to numerical dating, e.g., by means of uranium series in the case of travertine deposits or by application of luminescence procedures in the case of loessic deposits. A larger age characterizes early stages of hominid evolution as evidenced by the occurrence of australopithecines. Such discoveries can be dated using only a few methods, e.g., the potassium–argon method ($^{40}$K/$^{40}$Ar), and as a result merely rocks and loose deposits of volcanic origin can be considered. This means layers of lava rocks and tephras can be dated at sites of fossil hominid remains, where such layers are included in the stratigraphic sequence. Thus, the object of dating is not fossiliferous deposits but distinct layers in the sequence that includes fossiliferous deposits. Ergo, the chronological
investigation is restricted to time-marks in the local stratigraphy of the respective site (cp, e.g., Fitch and Miller 1976; Ullrich 1983: fig. 3).

14.5 Global stratigraphical context

The hominid evolution started more than 4 Ma (cp Johanson and Blake 1996 p 23), but according to previous conclusions of the International Union of Geological Sciences (IUGS) on the occasion of international congress meetings (London 1948; Moscow 1984), this time-span has been subdivided by the boundary between two different geological systems, i.e., the Tertiary and the Quaternary (Aguirre and Pasini 1985; Partridge 1997). The agreement of 1984 was prepared by another international congress meeting held by International Union for Quaternary Research (INQUA) likewise in Moscow in 1982 (Cepek and Jäger 1988). According to this agreement, the chronological position of this boundary has been settled at 1.64 or 1.8 Ma. Both the systems can be characterized by the common feature of long-term significant climatic fluctuations, but nevertheless they are distinguished noticeably by the average level of temperature oscillations according to their mean values, especially in middle and higher latitudes of the globe.

However, recently on behalf of the International Commission on Stratigraphy (ICS), a body of the IUGS with the competence for recommendations related to a world-wide geological timescale, a proposal was presented aiming at the removal of this stratigraphical boundary by extending the preceding system of the Neogene, i.e., the Upper Tertiary, up to the present (Gradstein et al. 2004). Nevertheless, there are serious objections to this proposal (Claque et al. 2004) regarding fundamental environmental changes during the discussed period (Gibbard 2004; Pillans 2004).

Independent of these current discussions, the actual fixation of the debated global stratigraphical boundary at 1.64 or 1.8 Ma seems to be an unfortunate decision (Cepek and Jäger 1988). The chronological base of the younger system or period may be defined more properly at 2.6 Ma (Gelasian stage of the Pliocene series of the Neogene so far: Pillans 2004).

14.6 Environmental dependences of sites

Climatic fluctuations over several hundreds of thousands of years, as mentioned above, determined not only the environmental conditions of previous hominids both in the temperate zones and in polar and subpolar regions but also influenced the human site selection and the chances of fossil preservation.
Varying climate conditions favored different processes of sedimentation and consequently different types of deposits.

This is why during long-term cold periods, the glacial advances of glaciers in subpolar and mountainous regions, was accompanied by periglacial and climatically continental circumstances in the lowlands and hilly uplands of midlatitudes favoring the eolian deposition, mainly of dust. Consequently, hominid finds from such glacial periods have been made rather frequently in loess sequences, as e.g., at Dolní Věstonice in the Czech Republic and in Austrian sites.

On the other hand, many sedimentation processes can take place under warm, frequently under warm and wet, environmental conditions only. The respective deposits could originate either under a constant warm climate, as in the tropics, in lower latitudes or in the warm phases of glacial cycles, the so-called interglacials, in the midlatitudes. This is why the interglacials have favored such deposits as travertine and peat. Travertines may be defined as consolidated fresh-water lime deposits, especially calcareous tufas.

As mentioned above, especially the travertines have provided excellent conditions for the preservation of finds, as well as for environment reconstruction. Moreover, the origination of these deposits required the proximity of springs and waters, due to the dependence of all fresh-water lime deposits on hard water. Owing to the significance of water for human life, sites of travertine formation were also frequently preferred locations of human presence and settlement. Consequently, man has often visited such sites and his remains can be discovered there frequently. Examples are in Central Europe, the well-known interglacial sites at Gáňovce, Tata, Taubach, Stuttgart-Bad Cannstatt, Weimar-Ehringsdorf, Bilzingsleben, or Vértesszöllös. Due to man’s presence and activities at such sites, they are significant not only when seen from a paleoanthropological angle but also as a result of archeological discoveries.

As a rule, interglacial deposits, such as peat, mud, or travertine, contain assemblages of floral and faunal fossils and thus provide chances of quantitative paleontological analyses. Differences related to age are reflected by differences of the assemblage composition recorded by pollen, conchylia, or micromammal bones and teeth. Consequently, suitable methods of quantitative paleontological analysis aiming at biostratigraphical indications and correlations are pollen analysis (peat, mud), paleomalacology and the investigation of micromammal remains (especially in travertines).

Considering differences related to the composition of flora and fauna accompanying fossil hominid remains, a relative chronology of sites may be based on biostratigraphy.

This viewpoint may be exemplified by the application of paleomalacology to famous interglacial travertine sites in Central Europe (Jäger and Ložek 2004),
including significant places of paleoanthropological discoveries (Jäger and Ložek 2005). Sometimes in this way a previous chronological assignation of single sites has to be corrected (e.g., Weimar-Ehringsdorf in Thuringia, Germany: at least Jäger 2001; cp in addition Mania 1993; Steiner 1993).

14.7 Archeological context

The majority of the sites providing fossil human remains, both from early hominids and from modern humans, have enabled archeological observations. To be precise, at many sites bones and teeth prove the previous presence of human beings, but at the same time accompanying archeological finds or man-made modifications of the site tell us about human activities, behavior, and lifestyle. This is why frequently at sites of paleoanthropological significance, archeological discoveries are also made. This is true both with reference to early hominids like Koobi Fora (in the Turkana Basin, Kenya: Coppens et al. 1976) or Hadas (Awash region, Ethiopia: Kimbel et al. 1982) and to later humans.

Since the Middle Paleolithic, a considerable share of the available evidence comes from burials. This dating means that even Neandertals are among the number of specimens recorded in this way (cp summarizing survey by Bosinski 1985 pp 44–52). In this context, among others the famous examples at Le Moustier and La Chapelle aux Saints in France, or the “Old Man” from the Shanidar cave in Iraq, may be mentioned.

During the Upper Paleolithic, the number of burials increased. Among them is a female individual who was portrayed in a contemporaneous ivory carving from the same Pavlovian site at Dolní Věstonice (Moravia, Czech Republic: Klima 1983 pp 83–89). During the Holocene comprising the last 11,600 years (Litt et al. 2001), *Homo sapiens* is represented not only by single burials but rather by multi-individual cemeteries of different age, occasionally comprising hundreds of burials or more (e.g., Hallstatt in Austria, Early Iron Age, mainly 8.–6. century BC—discovered are ca. 1,300 burials until 20. century AD: Kromer 1959; Sacken 1868; later Pauli 1975).

Burials favor the preservation of bones and teeth altogether, frequently even in the original articulation. Apart from burials, frequently the previous attendance of humans at the site of discovery could be proved for other reasons. The preselection of sites of later—or current—evidence could aim at the use of a sleeping site in the case of early hominids, which may be exemplified by the cave system of Swartkrans in Southern Africa (with finds of *Paranthropus* according to Brain 1983).
Later, humans frequently used the sites of record for settlement as well as for activities of everyday life, art, and other cultural purposes. Well-known examples have been recovered in caves as well on open ground.

An outstanding example of cave occupation by previous residents is given by the site 1 at Chou Kou Tien (Zhoukoudian) near the Chinese capital Beijing (Peking), well known as the eponymous site of the so-called Peking Man (Sinanthropus respectively Homo erectus pekinensis: Wei 1988; Huang 1998; Brühl and Laurat 2000 pp 94–100 and pp 9–10). However, evidence of Neandertal men found in caves has proven that these locations were both residential and burial sites. The former are usually distinguished from the latter by the irregular scattering of more or less isolated bones and teeth.

Moreover, the same feature also characterizes residential sites on open ground. However, if calcareous deposits are present in the subsoil to a greater or lesser extent, then such archeological sites also favor the preservation of bones and teeth and more frequently of isolated and often fragmentary objects.

In situ preservation of the original depositional conditions is provided especially at travertine sites (e.g., Vértesszöllös in Hungary: Kretzoi and Dobosi 1990; Bilzingsleben in Germany, recently Mania 1999; Weimar-Ehringsdorf, likewise in Germany: comprising Steiner 1981 and Vlček 1993) and at loess sections (e.g., Dolní Věstonice in Moravia, Czech Republic: Klima 1983; Vlček 1991).

Moreover, fluvial and deltaic as well as—rarely—marine deposits as a rule contain and provide not only isolated and more or less fragmentary but also dislocated parts of the human skeleton. Well-known examples are the famous early mandibles from Dmanisi in Georgia (Dzparidze et al. 1992; summarizing Justus et al. 2000) and from Mauer near Heidelberg in Germany (currently on the local situation: Fezer 1992; Zöller and Stremme 1992; Löscher 1996), as well as the cranium found at Steinheim/Murr in SW Germany (Adam 1988).

On the contrary, not only the preservation of the original articulation of bones and teeth but also of soft parts of the human body is realized frequently in the case of bog bodies (compare among others Hahne 1918; Dieck 1965; Glob 1969; Brothwell 1986; Turner and Scaife 1995; Gebühr 2002).

15 Zoogeography: Primate and Early Hominin Distribution and Migration Patterns

Alan Turner · Hannah O’Regan

Abstract

Human evolution may be usefully considered as part of the evolution of the larger mammalian fauna of the Tertiary and Quaternary periods. When viewed in this way, the dispersion of the hominins, and the questions of timings and directions, can be examined in the context of movements in other mammalian groups without being treated as special case with a unique set of causes. Earliest migrations by Primates into Africa during the Oligocene and Miocene were accompanied by numerous other taxa that were capable of crossing the closing gap between continents. While the later evolution of the Hominidae may well have taken place in Africa, the dispersion patterns of the Dryopithecine apes during the early Middle Miocene into Eurasia and then back into Africa toward the Late Miocene suggest a rather wider ancestry for humans and the living African apes. Earliest movements across the Gibraltar Straits during the Pliocene and Pleistocene can be ruled out for any terrestrial mammals, and while a Late Pliocene dispersal across the opening Bab-el-Mandeb region of the southern Red Sea may have been possible, such a route appears an unlikely choice for a Pleistocene gateway leaving only the Levantine route across Sinai as a plausible way out of or into Africa.

15.1 Introduction

It is a commonplace observation that species of both plants and animals have patterns of distribution, and that everything is not found everywhere (Cox and Moore 2004). In many cases, such distributions can be explained by the presence of physical or biotic barriers such as mountains, deserts, or water and the absence of suitable foods, while some clearly owe much to modern human interference.
But a species may not have always been where it is found now, while another may formerly have existed in areas from which it is now absent, so that many patterns reflect processes of movement that occurred from a few tens to thousands or millions of years ago. We live on a planet that has been constantly changing, as the continents have shifted and climates have altered, and it is likely that many of the patterns we observe today have been affected by such events.

Change in zoogeography over geological time, and its relationship to tectonic and climatic events, is one of the things that the fossil record can bring to providing a bigger picture of the past, although pitfalls must be overcome in the process. Identification and dating must be accurate, and while presence is clear enough from the fossils, firm evidence for absence in a region may be rather more difficult to distinguish from simple failure to look in the right place or simply to find. But the fossil record is never as good as it will become, and synthesis cannot forever be delayed on the grounds that we do not yet have enough data. As time goes on, and more evidence accumulates from more and more sites, even absence may start to be seen as a real feature of the record and attempts at synthesis of zoogeographic patterns may legitimately be made (Turner and Wood 1993).

Paleoanthropology deals with the evolution of us and our close fossil relatives, the tribe Hominini or hominins, and may be extended, according to the interests of the enquirer, to include the evolution of the Hominioidea (the superfamily that includes lesser apes, great apes, and humans) or even more widely to other Primates. The wider the context, we would argue, the better the understanding of any fossil group is likely to be. In the case of the Hominioidea, one of the most important issues to understand is the question of dispersions, whether of the Primates into Africa in the first place or our closer hominin fossil relatives out of Africa in the later stages of their evolution. The dispersals of the Hominioidea are thus likely to be best understood within the larger context of dispersals in other elements of the mammalian fauna, and our aim in this chapter is therefore to examine that larger context. We begin with a brief discussion of initial movement of the Primates into Africa and then go on to look at the evidence for Miocene to Early Pleistocene distributions within Africa and between Africa and Eurasia.

### 15.2 Early movements of Primates into Africa

Recent molecular analyses of DNA sequences suggest that a small number of mammalian orders (the elephants, hyraxes, tenrecs, aardvarks, elephant shrews, golden moles, and the aquatic manatees or sea cows) together compose a unique
group, the Afrotheria, whose members share a restricted common ancestry (Madsen et al. 2001; Murphy et al. 2001). The fact that the closest (sister) group to these is the South American order Xenarthra (the sloths, anteaters, and armadillos) makes sense in terms of continental separations and offers logical support to the identification of an Afrotheria. A significant absence from the Afrotheria, however, is the Primates, which seem to have evolved in the Northern Hemisphere (Fleagle 1999).

The Afrotheria owe their origins as a distinctive group to the fact that the continent was long isolated after the breakup of the southern landmass of Gondwana. Africa and the southern part of the Arabian Peninsula finally docked with the Eurasian plate in the Early Miocene, around 25–18 Ma, after a northward movement from the breakup estimated at around 14° of latitude (Rögl 1999). In the process of closing with Eurasia, the eastern arm of the Tethys seaway was closed, providing a land connection. At what precise point movements across the shortening gap between Africa and Eurasia became possible for terrestrial animals is unclear, but the Primates are known in some numbers from the Oligocene-age Fayum deposits of Egypt from as early as 33 to perhaps even 40 Ma, and an even earlier appearance around 45 Ma is suggested by material from Algeria (Godinot and Mahboubi 1992). The implication is that some form of island hopping across the shortening gap was possible as tectonic forces buckled the floor of the Tethys and produced a series of small and no doubt short-lived areas of dry land. Following the contact between Africa and Eurasia, a transgression of the Tethys Sea southward left Africa connected to Eurasia via the southernmost part of the Arabian Peninsula across what are now the Bab-el-Mandeb Straits (Tchernov 1992). Much of the later Miocene movement of faunas into and out of Africa therefore probably took place across this region, although our knowledge of the Miocene mammalian fauna of Arabia is currently very poor (Whybrow and Clements 1999).

Those same enormous forces produced by the combined northward movement of Africa and India formed the mountain chains that run from southern Europe to the Himalayas, including the Taurus and Zagros mountains of Turkey and Iran that have combined with the frequently harsh conditions of the Arabian Peninsula to control movements into and out of Africa (Tchernov 1992) (see also later). Toward the end of the Miocene, during the Messinian salinity crisis, tectonic processes in the westernmost region closed the portal with the Atlantic and the Mediterranean began to dry up (Kirksman et al. 1999). During the Early Pliocene the Mediterranean refilled, while the Red Sea widened as the Arabian plate swung away and eventually broke the Bab-el-Mandeb land bridge in the Late Pliocene, part of the eastern African rifting process that continues to the present day. Although some form of land bridge therefore existed between southern Spain and northern
Africa at some point during the Messinian, there is no compelling evidence for one across the Gibraltar Straits since then. Most if not all subsequent mammalian movements between Africa and Eurasia during Plio-Pleistocene times are therefore likely to have been via the Levant and perhaps Arabia (see later).

The better-known Primates of the Fayum were already quite diverse (see Rasmussen Vol. 2, Chapter 3). Numerous genera have been recognised, but their relationships to modern primates have yet to be established. Such diversity points to a well-established presence at that point, but the subsequent record of monkeys is poor until well into the Miocene, when records recommence in the rich deposits of eastern Africa where numerous remains referred to the family Victoriapithecidae occur (Benefit 1999). Primitive apes appear in the fossil record of Africa a little later than the monkeys, and there is a reasonably good record from Late Oligocene to mid-Miocene deposits. One of the oldest specimens comes from Lothidok Hill in northern Kenya, in deposits that may be as early as 27 Ma, while others are found at a range of Early Miocene sites in Uganda and Kenya such as Rusinga Island in what is now Lake Victoria, at Koru and at Songhor in deposits dated to the period 22–17 Ma (Andrews and Humphrey 1999). These animals, belonging to the genera Proconsul, Rangwapithecus, and Nyanzapithecus and varying from large monkey-like up to female gorilla-like in size, are placed in the separate family Proconsulidae and best characterized as “arboreal quadrupeds” (see Ward Vol. 2, Chapter 9).

More advanced apes belonging to the family Hominidae appear in a further radiation in the period 17–12 Ma. They have been referred to the subfamily Dryopithecinae and divided into the tribes Afropithecini, Kenyapithecini, and Dryopithecini, although Andrews (1996) argues for elevation of all to subfamily status, and it is at this stage that we see first evidence for a return movement of Primates out of Africa. Although the Afropithecini occur in Africa and Arabia, the Kenyapithecini are known from Kenya but mostly occur in Turkey and southeastern Europe while the Dryopithecini are European in distribution. In other words, the major known dryopithecine distribution is outside Africa. As we shall show later, this early dispersion from Africa may have implications for our understanding of the later origins of the Homininae, the subfamily containing the African great apes and humans.

The earliest movement of the Primates into Africa may have been “accompanied” by a dispersal of the archaic predator order Creodonta, since members of the family Hyaenodontidae also first appear in Late Eocene deposits there, but further contemporary incursions of other groups are not evident. A clearer pattern emerges at the time of full contact around 20 Ma, when other immigrants from Eurasia included the first perissodactyls in the form of early rhinos, and the bizarre-looking chalicotheres, with their horse-like heads and clawed feet. More
artiodactyls also made their appearances, with the incursion of the giraffoide climactocerids and first antelopes as well as primitive pigs of the genus *Nguruwe*, which must have traversed the continent since they are known from Namibia and Kenya at around 17.5 Ma (Turner and Antón 2004). More advanced cercopithecoid monkeys replaced the earlier Primates, although in situ evolution is hard to distinguish from immigration. True Carnivora entered the continent with the first appearance of cats and the amphicyonid bear-dogs as well as of mustelids (Morales et al. 1998) and, at least in North Africa, of members of the extinct cat-like family Nimravidae, although the creodonts continued to prosper as the dominant meat eaters. In the other direction, the probable dispersion of dryopithecine apes was perhaps preceded by the appearance of anthracotheres in Europe and possibly accompanied by a dispersal of monkeys of the genus *Pliopithecus*, the creodont *Hyainailouros* and the first movement of the proboscideans from Africa (Agustí and Antón 2002). The latter consisted of movements not of elephants proper but of the four-tusked gomphotheres and the deinotheres, the latter marked by a single pair of tusks set in the lower jaw. The subsequent history of some of the various proboscidean genera during the Miocene and Pliocene suggests a good deal of interchange with Eurasia.

On a general note, the structure of the African Early Miocene guild of larger carnivores seems to have divided into flesh eaters among the early cats, nimravids and perhaps smaller creodonts, and bone-crunchers among the amphicyonids and larger creodonts, and by the mid-Miocene the complexity in the guild structure of carnivores was enormous. Such a guild points to an equivalent complexity in the ecological relationships of predators and prey in Africa at this early period. The ungulates do not look particularly well adapted for speed while the predators do not look equipped to chase anything moving particularly fast. Dog-like animals, in the form of some of the smaller hyenas of the genera *Ictitherium*, *Hyaelictitherium*, *Lycyaena*, and *Hyaenictis*, only appear much later in the Miocene (see later) and in the absence of the true dogs of the family Canidae until later still in the Pliocene it is difficult to assess the extent to which pack hunting might have been possible (Turner and Antón 2004). The larger amphicyonids are unlikely to have operated cooperatively and would probably have taken a mixture of carrion and hunted meat. Overall, the zoogeography that we can piece together supports interpretations of the earlier to Middle Miocene vegetation of Africa as generally quite closed (Cerling 1992; Cerling et al. 1997). We might therefore presume that most of the Primates at that time would have found food and refuge among the closed vegetation, and as such have been fairly safe from predation, although some of the earliest cats were small enough to be effective climbers and may have found small monkeys, at least, an attractive target.
15.3 Zoogeographic evidence for the origins of the Hominidae

Africa is usually taken to be the origin point of the human lineage, and so far as the later stages of the Pliocene and Pleistocene are concerned this is generally accepted as true beyond reasonable doubt. Nevertheless some doubts about this matter have been raised in recent years—in particular regarding the origins of *Homo erectus* (White 1995; Dennell 2004)—and it would always be unwise to assume that the fossil record will never surprise us. We return to this point later below. However, as we have seen, the Primates themselves did not originate in Africa, and while emphasizing their incursion during the Oligocene or perhaps even the Middle Eocene may seem like an academic nicety, it is worth stressing that the intermediate period of the mid- and later Miocene witnessed emigrations and perhaps also reimmigrations.

The apes of the subfamilies Dryopithecini and Kenyapithecini that dispersed from Africa underwent a considerable radiation in Eurasia until the end of the Mid-Miocene, around 7–9 Ma (Andrews and Bernor 1999), but in Africa apes are scarce between perhaps 15 Ma and a reappearance at Lothagam at the very end of the Miocene (Andrews and Humphrey 1999; Leakey and Harris 2003). Interpreting such absence in the fossil record is always hazardous, since it may indicate no more than an absence of suitable deposits or inadequate search and recovery. But if it is a real pattern then it is perhaps among those Eurasian advanced hominid apes that we should expect an ancestor for the later great ape and human lineage of the subfamily Homininae. The possibility that the European Dryopithecini make the most plausible candidates has been both proposed (Begun 1993) and questioned (Andrews 1992, 1996; Andrews and Bernor 1999) on several details of taxonomy and systematics, but Solounias et al. (1999) have raised the question again in the context of understanding wider issues of the relationship between faunas of southeastern Europe and Africa. The latter authors point out that many of the savanna-dwelling mammals of Africa may well have originated in what they term the Pikermi Biome, based on the rich Late Miocene Greek locality of Pikermi. They cite somewhat longer necked and thus more advanced giraffes, rhinos of the extant genera *Diceros* and *Ceratotherium*, the false sabretoothed cat *Dinofelis* and the larger bone-smashing hyenas *Belbus beaumonti* and *Adrocuta eximia* as offering primary evidence for such an origin, and it is indeed clear that such animals do make their first appearance in Africa in the latter part of the Miocene. Overall, by around 8 Ma, over the middle part of the Miocene, there is an evidence of considerable incursion from Eurasia generally into Africa if we add to the above list the smaller to midsized and dog-like hyenas of the genera *Protictitherium*, *Ictitherium*, *Hyaenictitherium*, *Lycyaena*, and *Hyaenictis*, the sabretoothed cat
Machairodus, a range of mustelids, and a number of antelopes (Vrba 1995; Werdelin and Turner 1996; Turner and Antón 2004). The impetus for this movement appears to have been a major shift in climate, changing the western European vegetation from subtropical evergreen forest to more deciduous and dry woodland and provoking a turnover in mammalian fauna that Agustí et al. (1999) termed the mid-Vallesian Crisis. By around 9 Ma, the dryopithecine hominids were extinct in Western Europe, although they managed to survive until perhaps 7.5 Ma in Italy and China (Andrews and Bernor 1999). A movement of early hominid apes back into Africa is therefore entirely plausible as part of this larger pattern of dispersion.

15.4 Zoogeography of African Pliocene Hominini

Whether or not the common ancestor of later Hominidae was indeed of Eurasian dryopithecine-like morphology and origin, our African ancestors and relatives changed from being generalized apes to more sophisticated apes with tools over a period of a few million years, only becoming really recognizably human with the earliest appearance of the *H. erectus* lineage at around 1.8 Ma. This transition included shifts to an upright stance and fully bipedal walking and a massive increase in relative and absolute brain size, presumably accompanied by alterations in behavior, social interactions, and intelligence. Details of zoogeography however remain unclear.

The earliest currently known putative hominins are the 7–6 Ma material from Toros Menalla in the Chad Basin referred to *Sahelanthropus tchadensis* (Brunet et al. 2002) and the 6–5.5 Ma *Orrorin tugenensis* from Lukeino in Kenya (Senut et al. 2001). The latter is thought to have been associated with wooded environments, but the Chad Basin paleoenvironment appears to have been more of a mosaic association of lake-side gallery forest, wooded savanna and open grasslands (Vignaud et al. 2002), and the precise preference of the primate is hard to determine.

According to interpretations of the material referred to the later *Ardipithecus ramidus*, first found in 4.4 Ma deposits of the Middle Awash Valley in Ethiopia (White et al. 1994, 1995), an attachment to a woodland habitat may have persisted until close to 4.0 Ma (WoldeGabriel et al. 1994), although it is worth stressing that the authors pointed to similarities to chimpanzee morphology in various features of the remains so that hominin status may yet be rejected. Material also referred to *A. ramidus* from 4.5 to 4.3 Ma sediments to the west of the Awash at As Duma (Semaw et al. 2005) is also said to be associated with moderate rainfall grassland and woodland/grassland, based on paleosols, soil
carbonates, and faunal elements. However, stable carbon isotope values for ungulate dental enamels at As Duma suggest not only browse but also a significant component of C_4 grasses in the diet, and we should beware of the dangers of a small number of early hominin localities misleading us about habitat preferences and true distributions. Further fragmentary material from the Middle Awash Valley dated to even older deposits, around 5.8–5.2 Ma, was referred to *A. ramidus* (Haile-Selassie 2001), but was later given status as a separate subspecies, *A. ramidus kadabba*, on the basis of still more primitive dental characteristics that would presumably place it even closer to a common ancestor of humans and chimps. More recently still, Haile-Selassie et al. (2004) have argued that this form should be referred to as fully separate species, *A. kadabba*, which they consider is very similar to *Orrorin* and *Sahelanthropus*, and thereby infer that Late Miocene diversity was less than would seem to be the case.

We do know that the physical and biotic environment within which the hominins were evolving was itself undergoing significant changes. Rifting, volcanic activity, and uplift were continuing to change the topography of eastern and southern Africa as they had throughout the Miocene (Pritchard 1979; Adams et al. 1996), and as a result of these changes and their interaction with climatic events the vegetation was opening out to provide the distribution and huge mosaic of habitats existing there today. Such physical and biotic changes underlie the distributions of the living African mammal fauna (Grubb 1999; Grubb et al. 1999) and must have had a major bearing on the zoogeography of the past (Turner 1995). Clearly, more open vegetation not only developed during the Pliocene but also became an attractive habitat for predators and in all probability early hominins (Turner and Antón 1999). The development of a stone tool technology can now be traced back in Africa to around 2.4 Ma at Hadar and the Omo Shungura Formation in Ethiopia and the Lokalalei Member at West Turkana (Kibunjia 1994), while the bones of large mammals from Bouri in Ethiopia have damage marks interpreted as hominin-inflicted by means of stone tools (Semaw 2000). What happens in terms of hominin development in the intervening period before such technology was developed, either to assist or to motivate the move to more open terrain, is unclear.

An analysis of the zoogeography of African Pliocene hominins within the larger context of distributions in the rest of the Plio-Pleistocene large-mammal fauna was undertaken by Turner and Wood (1993), prior to the more recent discoveries referred to above but based on a larger body of hominin species and known distributions. The evidence available then, as now, suggested that the genus *Australopithecus* was apparently geographically split, and represented by *A. afarensis* in eastern Africa and *A. africanus* in the south. The genus *Paranthropus*, taken by Turner and Wood to be monophyletic, was considered to be
represented by *P. robustus* and perhaps *P. crassidens* in the south and by *P. aethiopicus* and *P. boisei* in the east. More recent discoveries have extended the range of named hominin taxa in the eastern region but done little to alter that picture of regional distributions, although Bromage and Schrenk (1995) have extended the range of *P. boisei* southward to Malawi. A new and more primitive species, *A. anamensis*, has been identified at East Turkana and Kanapoi in deposits dated to around 4.0 Ma (Leakey et al. 1995) while another, *A. bahrelghazali*, has been recognized at Koro Toro in Chad in deposits of slightly later age (Brunet et al. 1996). A third species, *A. garhi*, has been identified in deposits of the Middle Awash Valley (Asfaw et al. 1999), and a fourth, placed in a new genus as *Kenyanthropus platyops* (Leakey et al. 2001), has been identified from deposits dated to 3.5 Ma at West Turkana.

In the case of the genus *Homo*, assessing the geographic distribution of species is made more difficult by the increasingly evident fact that the taxonomy is more complicated than has previously been assumed. *Homo* is conventionally considered to be evident in Africa back to about 2.5 Ma, first represented in eastern Africa by the species *H. habilis* and *H. rudolfensis*, although the latter has also been identified in Malawi by Bromage and Schrenk (1995). The fact that stone tools appear in the archeological record at about the same time has led to speculations about the relationship between evolutionary change and the development of tool-making abilities. However, it has long been apparent that the earliest taxa assigned to the genus *Homo* are a rather heterogeneous group (Wood 1991, 1992), and arguments that they be removed from *Homo* altogether have recently reemerged, in a scheme leaving *H. erectus sensu lato* as the earliest clear member of the genus (Wood and Collard 1999). This would place the first evidence of our genus almost precisely at the Pliocene–Pleistocene boundary and some time after the earliest appearance of stone tools, and of course it is this seemingly abrupt appearance of *H. erectus* that has led to suggestions of a possible origin outside Africa referred to above (White 1995; Dennell 2004).

Of course, tool making by hominins of other genera is neither improbable nor implausible. Chimpanzees both make and use tools, albeit primitive ones that satisfy any sensible definition of such behavior, and it may be that a variety of evolutionary solutions that included some elements of manufacture and use of technology were developing among the African Pliocene hominins (Turner and Antón 2004). While our own lineage moved toward greater ecological generalization coupled to an emphasis on stone tool technology and an increase in brain size, members of the genus *Paranthropus* appear to have developed larger jaws and teeth in order to cope with their food. At least one hominin species traditionally referred to *Homo*, the east African *H. rudolfensis*, appears to have followed the same path as the paranthropinines between 2.5 and 1.8 Ma with enlarged
teeth but with a relatively large brain as well. If the *H. rudolfensis* material is indeed to be linked to the earlier *K. platyops* and referred to that genus, as suggested by Leakey et al. (2001), we may then very well have evidence of a separate lineage within which brains and teeth both developed. We may therefore identify at least three different evolutionary developments within Pliocene hominins, all of which enjoyed a considerable measure of success.

Whatever the lineages involved, making sense of the zoogeography of Pliocene hominins is difficult. The record presents a complex series of morphologies and proposed taxa, and interpretations of identity, relationship, and adaptations of the various species, leave alone distributions, are impeded by the fragmentary state of much of the material and the fact that several taxa or putative taxa are represented by single specimens or localities. This underscores the value of looking at distributions within the rest of the fauna in order to see whether patterns that may appear to be present in the hominins make sense in terms of larger-scale patterning. The investigation by Turner and Wood (1993) extended to include just such a larger patterning in eastern versus southern African taxa and concluded that there was evidence for a high degree of regional differentiation in some families, particularly the Bovidae, coupled with evidence for significant dispersals in others. Among the Primates, the papionin monkeys appeared to show the most evidence for dispersals, and overall it was apparent that regional isolation was not a matter of rigid demarcation. The implications of this for our understanding of hominin biogeography are that regionally restricted taxa would be a plausible interpretation of the material to hand, but that movements between regions are likely to have occurred and that identified genera such as *Australopithecus* and *Paranthropus* with differing species in each regions are indeed likely to be monophyletic. If monophyly is a correct interpretation, then a localized origin with subsequent dispersals is likely to have been the dominant pattern (Turner and Paterson 1991; Turner 1999a).

The known distribution of Pliocene and perhaps Late Miocene hominin remains now stretches from Chad down through eastern Africa to South Africa, perhaps even from the Atlantic coast of the western Sahel down to the Cape as Brunet et al. (1995) argued, and any reasonable interpretation of that pattern would recognize it as a minimal statement of range. But how much the gaps in between known localities were filled in, or the limits of distribution extended, remains unknown, although we seem to have no evidence for occupation of the northwestern region prior to ca. 1.0 Ma (Raynal et al. 2001). Dennell (2004) has even suggested that if Pliocene hominins were in Chad some 2,500 km west of the Rift Valley by 3.5 mya then why not as far to the north or east by the same period? This, of course, would place them in Arabia or even southwestern Asia.
15.5 Out of Africa

The number, timing, and direction of earliest hominin dispersals from Africa have long been a major point of discussion, and opinions on these topics remain varied and contentious (Rolland 1998; Turner 1999b; Bar-Yosef and Belfer-Cohen 2001; Strauss 2001; Villa 2001; Dennell 2003, 2004). Early Pleistocene assemblages from ‘Ubeidiya in Israel dated to around 1.5 Ma (Belmaker et al. 2002), perhaps Pakistan by 1.8 Ma (Dennell 2004), and human material from Dmanisi in Georgia dated around 1.75 Ma (Gabunia et al. 2001; Vekua et al. 2002) set a minimal date for the original movement. Dispersals to eastern parts of Asia remain more contentious, with the most recent claim based on 1.66 Ma deposits at Majuangou in the Nihewan Basin of northern China with stone implements and what is interpreted as stone-tool processing of animal carcasses (Zhu et al. 2004). The stone tools resemble primitive Oldowan items found in African deposits, and the authors argue for a significant and flourishing early dispersion from Africa, although the rest of the mammalian fauna has no clear African elements. However, the current consensus would seem to favor a shorter chronology after around 0.5 Ma for more extensive and intensive occupation of Europe in particular and Eurasia in general, with a long tail of more sporadic appearances back to and perhaps even beyond the Plio-Pleistocene boundary (Turner 1999b; Roebroeks 2001). But which route, or routes, was used? By land across Sinai and the Levant, across the Bab-el-Mandeb Straits at the south of the Red Sea and then across the Arabian Peninsula proper, or by the Gibraltar Straits?

15.5.1 Gibraltar

Although the evidence available points to some part of the Arabian Peninsula as the most probable route for Plio-Pleistocene hominin dispersions, various claims for possible movements across the Gibraltar Straits have been made most recently by Rolland (1998). He argues for a reduction of the seaway through the Straits to 8 km during glacial maxima, without any increase in surface current and for sweepstake-like movements, especially during OI Stages 12 and 16. Flemming et al. (2003) argue that the Strait itself would not have narrowed significantly during sea-level falls, although they point out that now submerged areas to the west of the Strait would have formed substantial islands that might have provided “stepping stones.” Strauss (2001, p 99) offers a thoughtful analysis of the issue but concludes that the record for human contacts is “at best spotty and ambiguous.” As far as other routes across the Mediterranean are concerned, particularly between Tunisia and Sicily, Flemming et al. (2003) reach no conclusion, and it is not evident that such possible
routes have any strong scientific support. Villa (2001) provides a useful summary of some of the arguments and rejects the idea of such routes.

As summarized elsewhere (O’Regan et al. in press), among the extant and Holocene terrestrial mammals present in North Africa and Iberia, such as wild boar (*Sus scrofa*), red deer (*Cervus elephas*), otter (*Lutra lutra*) and the red fox (*Vulpes vulpes*), there are none that are not also present in the Levant. This suggests that these animals took a circum-Mediterranean route rather than crossing the Gibraltar Straits (Dobson 1998), although of course the possibility of some individual animals swimming across cannot be completely ruled out. Some bat species are found on both sides of the Straits and further eastward in Europe but are not recorded in the Levant or elsewhere in North Africa, which could imply dispersion across the Gibraltar Straits (Dobson and Wright 2000). However, the extent to which recent human interference has played a part remains a concern, and of the 17 terrestrial mammal species inhabiting North Africa today only 4 are considered to have a natural circum-Mediterranean distribution whereas the rest are thought to be recent introductions (Dobson 1998). Clearly, if populations of *H. sapiens* were capable of dispersing over substantial bodies of water to reach Australia in the Late Pleistocene (Bowler et al. 2003), then it is also possible that they may have been moving around the Mediterranean and transporting animals prior to the Holocene, a point stressed by Strauss (2001). However, we believe that the Gibraltar Straits cannot be shown convincingly to have been the scene of natural Pliocene, Pleistocene, or even Holocene movements of terrestrial mammals and that the Arabian Peninsula remains the only established route of a two-way movement between continents.

**15.5.2 Arabia**

In contrast, the possibility of hominin dispersions through the Arabian Peninsula and the Levant, either across the Sinai Peninsula or the Bab-el-Mandeb Straits at the south of the Red Sea, is indicated by the mixed Afro-Eurasian nature of the fauna of the region since the later part of the Pliocene and in particular by the Early Pleistocene deposits at ‘Ubeidiya in Israel (Tchernov 1992; Turner 1999b; Belmaker et al. 2002). Late Pliocene African elements, chiefly bovids and giraffids, are known to the north of the Taurus-Zagros mountain chain that borders the northern boundaries of the Arabian Peninsula at localities such as Kuabebi in the Caucasus and Wolacks in Greece (Sickenberg 1967), the Oltet Valley in Romania (Radulesco and Samson 1990) and Huélagó in southern Spain (Alberdi et al. 2001). The dispersals represented by these occurrences appear to have been part of a larger faunal turnover in Eurasia, what Azzaroli et al. (1988) termed the
Elephant-\textit{Equus} event in Europe, since it was thought to be marked by the first appearance of \textit{Mammuthus} and the true horse, \textit{Equus}, although the first appearance of these genera now seems to have been somewhat earlier (Radulesco and Samson 1990, 2001).

At Dmanisi, the African elements consist of a giraffe, \textit{Paleotragus} sp. (Gabunia et al. 2001), and at Ubeidiya an undetermined giraffid, the bovids \textit{Pelorovis oldowayensis} and an oryx, the hippo \textit{Hippopotamus gorgops}, and perhaps the spotted hyena, \textit{Crocuta crocuta} (Tchernov 1992). The Acheulean industry at Ubeidiya is unknown at Dmanisi and appears to have developed in Africa at a slightly later date. Other Early Pleistocene localities in Europe have relatively few African species. Much has been made of the appearance of the cercopithcoid \textit{Theropithecus cf. T. oswaldi} at Cueva Victoria in southeastern Spain (Gibert et al. 1995) and Piro Nord in Italy (Rook et al. 2004) and of the possibly African machairodont cat, \textit{Megantereon whitei}, at Venta Micena and in the fauna at Dmanisi and at the Greek locality of Apollonia (Martínez-Navarro and Palmqvist 1995, 1996). However, while \textit{Theropithecus} may indicate African links, the genus \textit{Megantereon} was a well-established member of the Afro-Eurasian carnivore fauna after around 3.0 Myr (Turner 1987) so that claims for its significance in the question of dispersals require further investigation. Of rather more obvious importance is the presence of \textit{Hippopotamus}, which makes an early appearance at the Pliocene locality of Valea Graunceanului in Romania (Bolomey, 1965), and at several the Lower Pleistocene sites such as ‘Ubeidiya and Venta Micena (O’Regan et al. in press).

Overall, we conclude that the suggestions of possible hominin dispersions into Eurasia during the later Pliocene that appear in the literature from time to time (Bonifay and Vandermeersch 1991; Boitel et al. 1996), while unsupported by critical assessments of the evidence within Eurasia, cannot be dismissed \textit{a priori} as impossible or even unlikely. These conclusions parallel some of those reached by Mithen and Reed (2002) in their computer simulation of dispersals and stressed elsewhere (Dennell 1998, 2004). If recent arguments summarized earlier about the status of later Pliocene species referred to the genus \textit{Homo} are correct, then clearly the earliest hominin to have moved out of Africa would not have been a member of our own genus. However, whether such a view offers support for an extra-African origin for \textit{H. erectus} remains unclear to us.

\section*{15.5.3 Precise routes}

If Arabia is indeed the only plausible route out of Africa for terrestrial mammals during the Plio-Pleistocene, it remains difficult to judge the relative contributions
of the Sinai versus the Bab-el-Mandeb as gateways. In a recent paper, Petraglia and Alsharekh (2004) outline some of the problems that beset understanding the Middle Paleolithic or later Middle Pleistocene hominin occupation of Arabia, and the relative paucity of evidence for Lower Paleolithic occupation at the small number of known localities. However, as Petraglia (2003) also showed, both Oldowan and Acheulean assemblages are known, and the eastern side of the Bab-el-Mandeb Straits in particular appears to have been occupied by hominins with this technology. Unfortunately, the absence of good chronological control remains a major obstacle to assessing the pattern of lithic assemblage distribution, while research focus and the difficulty of fieldwork add to problems in overcoming our lack of knowledge of the area. But while these obstacles to understanding are clearly real, it remains hard to believe that much of the Peninsula was exploitable for much of the time by latest Pliocene or Early Pleistocene hominins.

As Petraglia and Alsharekh (2004) show, while movement across Sinai offers the possibility of movement along the Levant and then perhaps south into Northern Arabia either along the eastern Red Sea Coast or inland behind the highlands of the Hejaz Asir, movement across Bab-el-Mandeb confronts any dispersing population directly with the highlands. These would tend to restrict movement to the coastal strips, north along the eastern Red Sea Coast or east along the Arabian Sea Coast. While annual rainfall today in the Hejaz Asir or in the Oman Mountains at the easternmost corner of the Peninsula can reach well over 100 mm, much of the southeastern portion, the Rub Al Khali or empty quarter, may have no more than 50 mm with temperatures that exceed 50°C (Glennie and Singhvi 2002). The fact that Lower and Middle Paleolithic occupation did occur means of course that conditions were not always unfavorable, and as Glennie and Singhvi show, the presence of substantial alluvial fans suggests that some earlier interglacials may have been more humid than today, although again the lack of chronological control hampers interpretation. We also know little of the Plio-Pleistocene fauna of Arabia, which is even more sparsely represented than that of the Miocene. The sole exceptions are the small assemblages from An Nefud in northern Saudi Arabia, thought to be of Early Pleistocene age (Thomas et al. 1998) and which, with spotted hyena, hexaprotodont hippo, horse, elephant (cf. *Elephas recki*), several bovids including a species of *Pelorovis* as well as crocodile and fish, are of distinctly African stamp. The range of species implies good grassland and standing water in the vicinity, an interpretation supported by isotopic analyses of herbivore teeth.

However, as Glennie and Singhvi also point out, increased aridity is indicated during glacial periods, beyond even that seen today despite the fact that temperatures may have averaged somewhat lower, and this factor presumably played a large part in determining the extent to which mammals, including early
hominins, could maintain any occupation throughout the Pleistocene. Glacial periods with their massive falls in sea level are of course precisely the point at which the Bab-el-Mandeb crossing is likely to have been at its most obvious and navigable to early hominins (Rohling et al. 1998; Cachel and Harris 1998), so that the easiest and most attractive access by that route is likely to have been at a point when conditions in southern Arabia, and for that matter on the corresponding coastal area of Africa, are likely to have been least appealing. Taken overall, the Bab-el-Mandeb Straits do not seem likely to have offered a likely gateway out of Africa for terrestrial mammals during the Lower and Middle Pleistocene, suggesting that movement across Sinai and then northward along the Levant, southward into Arabia, or eastward and beyond is the most plausible route. However, movement across the Bab-el-Mandeb during the later Pliocene, before the Straits had fully formed, and thus before the crossing into Arabia was dependent on sea-level fall, may have been an entirely different matter, as previously pointed out (Turner 1999b). The importance of the Afar region of Africa to the south and west of Bab-el-Mandeb as an area of attractive resources for mammals, including hominins, following rivers into the developing depression as rifting progressed from Miocene times onward was highlighted by Kalb (1995, p 366), who stressed “the step-by-step process of animal migrations into and dispersal across intercontinental areas prior to complete plate separation.”

15.6 Conclusions

It seems clear to us that the wider context of movements between Africa and Eurasia throws useful light on the patterns of dispersion within Primates in general and Hominoidea in particular so that we can examine changes in primate distribution without having to treat them as a special case. In the earliest stages of the Oligocene and Early Miocene, we see that movements into Africa are accompanied by a range of other taxa and that the nature of the earliest guild of mammalian predators would perhaps have posed little threat to a largely arboreal range of Primates there. If dryopithecine apes first moved back into Europe during the Mid-Miocene and then back again into Africa toward the end of that epoch, then they did so as part of a much wider dispersal across a range of mammalian orders.

Our current knowledge of Pliocene hominins is at best incomplete, and while recent discoveries have extended the range of named species, they have done little to clarify the likely relationships between those taxa or the true nature of distributions. With the greater number of putative taxa now available, we suspect that it will require some considerable time and quite a few more discoveries
before real sense can be made of the patterns. However, as far as movement out of Africa by hominins is concerned, we believe that a number of points can be made. The Gibraltar Straits are unlikely to have been the site of any Pliocene or Pleistocene gateway for terrestrial mammals; and while movement across the Bab-el-Mandeb region before the Red Sea opened fully toward the end of the Pliocene may have been possible, dispersal across the Straits once the glacial and interglacial cycle got underway seems to us unlikely. Sinai and the Levant, the scene of a two-way faunal movement between continents during the later Pliocene, remains the only established route. Moreover, the diversity of elements using that gateway points to the relatively hospitable nature of the area in the later Pliocene, so that suggestions of possible hominin dispersions into Eurasia during the later Pliocene are not inherently implausible. However, how long any dispersing populations were able to maintain their extended range is entirely another question. We suspect that early hominin movements into Arabia and the Levant were sporadic and probably tenuous and that subsequent movements out into Eurasia proper were probably even more so.

Abstract
The history of life on earth, from the earliest microscopic cells to the modern world populated by the rich variety of animals, plants, fungi, and microbes, is more than 3500 Myr long. Documenting the diversity patterns through the Proterozoic and Phanerozoic has been a major task in the past decades and is fraught with many methodological problems. The emergent picture is one of a very irregular increase in diversity. The most significant episodes of diversification occurred during the Cambrian–Ordovician and throughout the Mesozoic–Cenozoic. In the Phanerozoic alone, 5 major and more than 15 smaller mass extinctions disrupted the diversification of life and sometimes drastically altered the way of evolution. There was no common cause for these events, but all were the consequence of large-scale environmental perturbations. There is growing concern that we are currently entering a “Sixth” major extinction, caused by human impact on nature.

16.1 Introduction
This chapter reviews the history of diversity, the “ups and downs” of life, during the past 3500 Myr. There are many reasons why the history of life’s diversity on earth is an important avenue of paleontologic research. (1) Such studies can give us insight into the relative importance of various mechanisms of evolution. (2) The analysis of diversification and extinction can help to clarify the respective roles of biotic (intrinsic) versus abiotic (extrinsic) factors. (3) The importance of regional versus global patterns/mechanisms can be investigated. (4) The analysis of extinctions might enable us to see if there are common patterns. (5) The possibility that Homo sapiens is causing yet another mass extinction fosters interest in other such events in the geological past.

One emergent theme when documenting patterns of diversification and extinction is that the major disruptions/discontinuities were not the consequence of some lineages’ “racial senility” or “genetic exhaustion” but rather caused by
large-scale environmental perturbations. The world as we know it today with its current climatic, atmospheric conditions, and present-day biosphere is not a good actualistic example for the remote past, where sea levels and mean annual temperatures were vastly fluctuating, continental plates had entirely different positions, and CO\textsubscript{2} and O\textsubscript{2} levels in the atmosphere showed secular changes.

This chapter is organized as follows:

- First an overview of major events in the history of life is given, together with an overview of changes in abiotic conditions. Here some emphasis is placed on the Precambrian.
- The patterns of diversification of Phanerozoic life is reviewed, most extensively for marine animals with preservable hard parts.
- Methodological problems in documenting diversity (as a measure of taxonomic richness) through time are discussed.
- In a special subchapter, some of the most important radiations and extinctions are treated in stratigraphical order.

16.2 **A short history of life on earth**

The earth is roughly 4600 Ma old ([Figure 16.1](#)), and the oldest rocks currently recognized (Acasta gneiss from the Northwest Territories, Canada) are dated as 4030 Ma (Nelson 2004). The earliest Eon of earth history, the Hadean, thus left no directly observable documents. It is nowadays assumed that the initially high temperatures following the accretion of the earth dropped around 4000 Ma below 100°C. During the earliest Archean, the surface temperature was probably quite low (faint early sun). By that time, liquid water was present on the earth’s surface, brought to the earth by comets (McClendon 1999). Yet the heavy bombardement with bodies exceeding 250 km lasted until 4200–3800 Ma. This must have led to repeated boiling of the oceans and the vaporization of the water (Nisbet and Sleep 2001, 2003).

Contrary to earlier beliefs (e.g., those assumed in the famous Miller experiment), most researchers today think that the Hadean and early U.S atmosphere was only mildly reducing, with mainly CO\textsubscript{2} and N\textsubscript{2}, but also smaller amounts of CH\textsubscript{4}, NH\textsubscript{3}, H\textsubscript{2} present (McClendon 1999; Raven and Skene 2003). Free oxygen builded perhaps through photodissociation of water vapor in the upper atmosphere but quickly reacted with Fe\textsuperscript{2+} and other unoxidized compounds. The early atmosphere was, therefore, devoid of free oxygen (McClendon 1999; Miller and Lazcano 2002).
Figure 16.1
Major events in earth history over the past 4600 Ma. Modified after various sources.
Under these conditions life originated (for reviews see Oró et al. 1990; Brack 1998; McClendon 1999; Fenchel 2002; Taylor 2005). Organic compounds could form in the atmosphere through UV-photolysis, electrical discharges, and major impact shocks (McClendon 1999; Lazcano 2001), and a major source of organic molecules was probably also comets and interplanetary dust (Lazcano 2001; Miller and Lazcano 2002), but early life certainly evolved in the sea (Raven and Skene 2003), and the first cells were probably heterotrophs (Lazcano and Miller 1996; but see Huber and Wächtershäuser 1997; Wächtershäuser 2000). As possible sites where cellular life evolved from prebiotic precursors, continental thermal springs, volcanic vents, warm hypersaline lagoons (Darwin’s “warm little pond”), and deep submarine vents are the most likely candidates (Schopf 1999). In this respect, it is noteworthy that the earliest branches of both the Archea and Bacteria are thermophilic (Pace 1997). Yet an extraterrestrial origin of cellular life cannot totally be excluded (Horneck 2003).

Perhaps life originated sequentially several times but was always exterminated by the heavy meteorite bombardment (“impact frustration”) until life took hold around 3900 Ma (Schopf 2002). The “Universal Ancestor” might have been a diverse community of cells that experienced extensive horizontal gene transfer (Woese 1998, 2002). Organismal lineages established themselves only with the subsequent splitting into the three domains “Bacteria,” “Archea,” and “Eukarya” (Woese 1998). The tree of life is thus at its base rather a web (Doolittle 1999) or even a ring of life (Rivera and Lake 2004).

The fossil record of the Archean is notoriously sparse. The presumed oldest cellular microfossils come from 3500 to 3450 Ma sediments in Western Australia (Schopf 1992a, 2004; but see Brasier et al. 2004). Almost as old (3400–3200 Ma) are microfossils in the metasediments of the Onverwacht and Fig tree groups (South Africa). From even older (3800 Ma) metamorphosed sedimentary rocks from Greenland (Isua Greenstone belt), putative microfossils (Isuasphaera) were described (Pflug 1978). Yet they are probably of inorganic origin (Bridgwater et al. 1981; Appel et al. 2003).

According to most authors (Mooers and Redfield 1996; Sheridan et al. 2003) the split between bacteria and archea–eukaryota must have occurred more than 3500 Ma (but see Doolittle et al. 1996). The Proterozoic fossil record (Hofmann and Schopf 1983; Mendelson and Schopf 1992; Schopf 1992a, b) documents an increasing diversification and complexity of cells but the evolution of metabolic pathways cannot be deduced from the morphology of the microfossils. Yet by 2700 Ma, oxygenic photosynthesis, methanogenesis, and methylotrophy had probably developed, perhaps also sulfate reduction and nitrogen fixation (Buick 2001).

In contrast to cellular fossils, the record of stromatolites is quite good. These are biosedimentary structures built by microbial mats which trap sediment
particles (Riding 1991; Walter 2001). The oldest stromatolites date from 3500 to 3200 Ma sediments in Australia and South Africa, but their fossil record remains spotty until the Neoarchean (Walter 1983, 2001; Grotzinger and Knoll 1999). They diversified considerably in the Proterozoic, and in the Mesoproterozoic, a large number of different types had developed, growing sometimes to impressive sizes (Awramik and Sprinkle 1999; Walter 2001). Stromatolites declined both in diversity and abundance in the terminal Proterozoic, and in the Phanerozoic, they remained largely restricted to marginal marine environments. This decline was traditionally seen as a consequence of the rise of the metazoans, which consumed the microbial mats, but it might also have abiotic reasons (Awramik and Sprinkle 1999).

2450–2200 Ma, the earth witnessed the first well-documented ice age, the Huronian glaciation. As a consequence of insufficient time resolution, the exact duration of glacial intervals during this Paleoproterozoic time period is unknown (Young 2004). The onset and the termination seem to have been gradual (Young 2004). Perhaps an increase in atmospheric oxygen (see later) was the cause of the Huronian glaciation (Kopp et al. 2005). If methane was a major contributor to a greenhouse effect prior to that time, it would have been oxidized in a more oxygen-rich atmosphere, and the removal of this greenhouse gas could well lead to global cooling and the onset of an ice age.

At some time between 2500 and 1900 Ma, the atmosphere changed rather abruptly from reducing ($pO_2 < 1\%$ present atmospheric level PAL) to oxidizing ($pO_2 > 15\%$ PAL; Figure 16.1), largely as a result of the activities of oxygenic photoautotrophs (Schopf 1992a; Holland 1994; for alternative scenarios of atmosphere evolution see Ohmoto 2004). Until about 2200 Ma, free oxygen was constantly removed by oxidation of weathered reduced minerals (Nisbeth and Sleep 2001; Lenton 2003). Detrital pyrite and uranite are common until 2200 Ma and indicate very low levels of free oxygen; otherwise these minerals would have been oxidized (Schopf 1992a; Holland 1994). Likewise, the genesis of banded iron formations (BIFs), which are absent in rocks younger than 1700 Ma, requires reducing conditions in the deeper parts of the seas (Simonson 2003).

The origin of the eukaryotes can be placed at some time before 2100 Ma. The oldest, currently recognized eukaryote is the 2100 Ma multicellular “algae” Grypania (Han and Runnegar 1992). Perhaps the origin of eukaryotes was linked to the increased oxygen content of the atmosphere and shallow waters where a nucleus and its protective membrane would be advantageous (Dyer and Obar 1994). Subsequent evolution of the eukaryotes took place by serial endosymbiosis (Margulis 1981) in which engulfed $\alpha$-purple-bacteria became mitochondria and cyanobacteria became plastids (Dyer and Obar 1994; Pace 1997). In part, even secondary endosymbiosis must have occurred in which photosynthetic eukaryotes were engulfed by nonphotosynthetic eukaryotes (Woese et al. 1990).
Little is known about the early evolution of the eukaryotes. Apart from the acritarchs that are a heterogeneous assemblage of planktonic, unicellular eukaryotes known from the Late Paleoproterozoic and extending into the Phanerozoic (Martin 1993; Knoll 1994), other fossils of the eukaryotic clade include various carbonaceous films that are not easy to interpret (Hofmann 1994). Yet new molecular dates, which are in reasonable agreement with paleontological findings, give some clues as to when new groups originated. The divergence between protists and crown-group plants may be as young as 1100 Ma, the origin of the fungi is placed at 1000 Ma, the split between choanoflagellates and eumetazoans occurred at 900 Ma, and the first bilaterians might have made their appearance at 700 Ma (Douzery et al. 2004; see also Peterson et al. 2004; Peterson and Butterfield 2005). Yet these dates are not universally accepted, and previous molecular-clock estimates have yielded considerably older dates (see review in Erwin and Davidson 2002).

Between 800 and 600 Ma, the earth witnessed several large glaciations. The last two episodes are well dated. The Sturtian glaciation occurred around 710 Ma, and the Marinoan (Varanger) glaciation ended at 630–600 Ma (Allen and Hoffman 2005). Some, perhaps most, continental land masses had a near-equatorial position at that time. Glaciers might have reached equatorial regions and perhaps extended down to the sea level. According to the most dramatic scenario (Hoffman et al. 1998; Hoffman and Schrag 2002; but see Chandler and Sohl 2000; Poulsen 2003), temperatures initially dropped due to some unknown mechanism, but as soon as glaciers reached a critical extension in low latitudes, enough solar energy was reflected back into space that ice sheets could grow at an ever increasing rate. In this “runaway albedo” model, not only all the land masses became ice covered, but the surface of the oceans were also globally frozen (“snowball earth”; Kirschvink 1992; Hoffman et al. 1998; Hoffman and Schrag 2002). The seas became anoxic and BIFs could accumulate again (Hoffman et al. 1998). Eventually, enough volcanic CO₂ accumulated, and the glaciations ended abruptly. Later Neoproterozoic glaciations are documented, but these were not global in their extent (Knoll et al. 2004).

Shortly after the last of these major Neoproterozoic glaciations, the first metazoans enter the fossil record. Enigmatic soft-bodied fossils 610–542 Myr old are known from localities around the world and named Ediacara assemblages (after the Ediacara Hills in South Australia). Although the nature of the flattened, segmented, or quilted Ediacara organisms is still disputed (mainly cnidarians and annelids; Glaessner 1983, 1984; Jenkins 1992; or organisms not related to any of the extant animal phyla; Seilacher 1989, 1992; Buss and Seilacher 1994), they are accompanied by traces produced by bilaterian metazoans (Knoll and Carroll 1999; Valentine et al. 1999; Martin et al. 2000). Yet tracemakers were small and
rare and did not disrupt the sediment. This only changed near the Precambrian–Cambrian boundary when bioturbation markedly increased and the sediment became unstable. This probably led to the extinction of the immobile Ediacara organisms (Seilacher 1999).

Within a short time after the beginning of the Cambrian at 542 Ma, the most remarkable episode in the history of life started, the so-called “Cambrian explosion.” Within only 20 Myr, all animal phyla with preservable hard parts (with the exception of the bryozoans) appeared (Knoll and Carroll 1999; Erwin 2001a; Valentine 2002, 2004). With the beginning of the Cambrian and continuing throughout the Phanerozoic, we have a very reliable fossil record especially for the marine invertebrates with easily preservable hardparts. Fossiliferous localities that show exceptional preservation are interspersed in the stratigraphical record and provide us with information on the soft-bodied fauna (Bottjer et al. 2002). Information on the Phanerozoic history of life can be found in most textbooks on paleontology and historical geology (Cowen 2005; Stanley 2005), and extensive treatment is beyond the scope of that chapter. Details on selected episodes of radiation and extinction are given in the last part of this chapter.

During the Cambrian, life was exclusively marine and dominated by trilobites and a variety of other arthropods. Because the trilobites were highly diverse, are easily determined, and show a high species turnover, trilobites are the most important index fossils for this period. Brachiopods were small and belonged mostly to the inarticulate groups. Among the mollusks, hyoliths and monoplacophorans were the most conspicuous ones, but in the Late Cambrian, the first small nautiloids appeared which marks the beginning of a highly successful group of marine predators. Cambrian echinoderms belonged mostly to groups that were immobile and became extinct during the early Paleozoic. Already during the Early Cambrian, the first true reefs built by the spongelike archeocyathans developed but archeocyathans became extinct at the end of the Early Cambrian, leaving a reef gap until the Middle Ordovician. The first chordates and agnathan fishes appear to have been rare with the exception of the conodonts.

The extinction events in the Late Cambrian affected most severely the trilobites and several echinoderm groups. Ordovician and Silurian seas became to be dominated by articulated brachiopods and stalked echinoderms (crinoids and blastoids). Although the first deep burrows appeared at that time, life was still mainly epibenthic. Large reefs dominated by tabulate and rugose corals and stromatoporoids developed, and bryozoans became an important component of marine hard bottoms. Among the planktonic organisms, the graptolites diversified considerably and have proven to be the most valuable index fossils for the Ordovician and Silurian. Large predators developed among the nektonic nautiloids and among the eurypterids. Several groups invaded freshwater
environments, among them the arthropods and various fish groups. Colonialization of the land started in the Silurian, first by plants (although algal crusts and fungi may have been present earlier), then by mites, arachnids, millipedes, and scorpions. Among the vertebrates, the appearance of the first jawed fishes in the Late Silurian was a major innovation.

During the Devonian and Carboniferous, land plants diversified in an explosive manner leading to the first true forests, and the first seed plants had developed by the Carboniferous. The first wingless insects appeared in the Early Devonian, but it was not until the Carboniferous that the first winged insects conquered the air. In the vertebrates, huge marine predators developed among the placoderms. The Devonian, also called the “age of fishes,” saw the first appearance of the chondrichthyan and actinopterygians while the agnathans considerably diversified. The first tetrapods appeared during the Late Devonian, and the amniote egg evolved in the Late Carboniferous. Among the marine benthic organisms, tabulate-rugose-stromatoporoid reefs attained a new climax. Articulate brachiopods and stalked crinoids still dominated most seafloors. Among the nektonic organisms, the evolution of the ammonoids was a major innovation during the Early Devonian. This group provided the most important index fossils for the Devonian to Cretaceous periods. In the latest Paleozoic, life in the seas did not radically change, but the absence of the heavily armored fishes is notable and among the cephalopods, the stoutly shelled nautiloids also declined while the ammonoids flourished. Reef building was confined to smaller constructs after the Late-Devonian mass extinction. On land, the mammal-like reptiles were the dominant herbivores and carnivores.

After the end-Permian mass extinction, life in the seas and on land dramatically changed. Seafloors were no longer dominated by epifaunal brachiopods and crinoids but by gastropods and burrowing bivalves. Reef production came to a halt during the Early Triassic, and it was not until the Middle Triassic that scleractinian coral reefs became established. This type of reef building would dominate throughout the rest of the Mesozoic and Cenozoic. Only during part of the Cretaceous were the corals replaced as principal reef builders by a group of aberrant bivalves, the rudists. The open waters were dominated by ammonoids and actinopterygian fishes, and during the Mesozoic, three groups of planktonic organisms which play an eminent role in the biogeochemical cycles made their appearance: the planktonic foraminifers, the coccoliths, and the diatoms. The largest creatures of the seas and the top predators were the marine reptiles: nothosaurs, plesiosaurs, ichthyosaurs, marine crocodiles, turtles, and mosasaurs.

On land, the conifers, cycads, and ginkgos flourished and dominated the forests until the late Early Cretaceous, when they became increasingly replaced by the flowering plants (angiosperms). Among the amphibians, the last stegocephalians
died out while the first frogs and salamanders appeared. After the end-Permian mass extinction, the mammal-like reptiles had become marginal players, and the archosaurs, most notably the dinosaurs, became the rulers of the earth. The pterosaurs were the first vertebrates to conquer the air by the Late Triassic, and in the Late Jurassic, the first birds evolved. Mammals arose already during the Late Triassic but remained mostly small and peripheral throughout the Mesozoic.

The mass extinction at the Cretaceous–Tertiary boundary, although much less severe than the extinction at the end of the Permian, nevertheless severely altered the structure of both marine and terrestrial ecosystems. In the seas, the shelled cephalopods became entirely extinct with the exception of a small group of nautilids, and from the marine reptiles only the turtles survived. The vacant ecospaces were filled up by actinopterygian fishes and mammals. The mammals also played a central role in the restructuring of the terrestrial communities. During the remarkable radiation in the Paleogene, mammals occupied almost all available niches on land, invaded the seas (whales, pinnipeds, sea cows), and conquered the air (bats). Birds equally radiated considerably, and in some regions large, flightless birds even became the top predators. After the Eocene–Oligocene climatic revolution, the flora and fauna had an essentially modern organization, and grasses as the most important terrestrial producers became widespread during the Miocene. The Miocene radiation of the apes ultimately led to the development of our species, *Homo sapiens*.

### 16.2.1 Directionality versus contingency

During the Precambrian, eukaryotes evolved from prokaryotes, and in the Cambrian, most animal phyla evolved. Ever more environments were colonialized during the Phanerozoic, including the land and the air. For the evolution of the vertebrates, the long-portrayed succession of the “age of fishes,” “age of reptiles,” and “age of mammals” is of course a gross oversimplification. Osteichthyans and chondrichthians were never as diverse as today! Yet although measuring morphological complexity is not straightforward, there was clearly a trend toward increasing complexity in the evolution of life from bacteria to today’s biota (Carroll 2001).

There are two fundamentally different views on this complexity increase. According to one view, the rise and ultimately dominance of complex life forms were an inevitable outcome of natural selection whereby more complex organisms outcompete the more primitive ones. It also inevitably culminates with the development of intelligent animals. Such a view is championed, e.g., by Conway-Morris (1998, 2003) and is reminiscent of an Aristotelian “chain of being.”
A radically different view of the evolution of life does not see complex mammals as superior to bacteria. The increase in diversity is not neglected but explained in a different way. Bacterial cells cannot evolve toward ever smaller sizes, unicellular eukaryotes cannot evolve toward zero cells but only toward multicellularity, and marine organisms cannot evolve to colonialize a nonexisting environment, but they can evolve land-dwelling species, and among animals also flying taxa. The evolution toward greater complexity is, thus, simply a move away from an “impermeable left wall” and an increase in variance, but in a sense we still live in a bacteria-dominated world (Gould 1996).

Perhaps the truth lies somewhere in between. There is no necessity to evolve toward intelligence, but ultimately this was made possible through successive evolutionary steps after the increasing variance crossed several thresholds. In such a view, life on earth followed a megatrajectory along the following sequence (Knoll and Bambach 2000): prokaryote diversification (including metabolic pathways, but inability for sexual reproduction), early eukaryote diversification (first consumers, multicellularity, increased size, sex), aquatic multicellularity (large size, packaging of biomass, fast movement, complex food chains), invasion of the land (huge biomass of producers, adaptation to widely fluctuating environments), and ultimately intelligence (which perhaps could also have evolved in the water). Nevertheless, if “life’s tape would be replayed,” the outcome would certainly be totally different (Gould 2001).

16.3 Diversity patterns: the broad picture

16.3.1 The current consensus

The 1970s and 1980s witnessed a veritable boom of publications which documented the diversity patterns of life during earth history, the pace of large-scale evolution. Yet the achievements of the late “Jack” Sepkoski clearly stand above those of all others at that time. His 1981 curve (Figure 16.2) of Phanerozoic diversity patterns of marine families (and subsequent refinements down to the genus level; Sepkoski 1996) is one of the most often reproduced figures in the paleontological literature (equaling perhaps the Berlin Archaeopteryx specimen; Benton 2001), and this benchmark is an ideal starting point for the discussion of life’s ups and downs during the last 542 Myr.

Assembling literature-based compilations of the worldwide temporal distribution of marine families (Sepkoski 1982, 1992) and genera (Sepkoski 2002), the number of described taxa and hence diversity for every successive stratigraphical interval (usually stages) could be determined. In addition, the
times of origination (first occurrence) and extinction (last occurrence) of these taxa could be deduced.

By means of a factorial analysis, Sepkoski (1981) could show that the marine families grouped into three rather well-delineated entities each showing a common pattern of origination, diversification, and decline. These three “Evolutionary Faunas” were called “Cambrian Fauna,” “Paleozoic Fauna,” and “Modern Fauna” (Sepkoski 1981). A division into finer intervals (nine “Ecological Evolutionary Units”) was suggested by Boucot (1983) and further refined by Sheehan (1996, 2001a); yet these intervals mainly portray ecological communities and not evolutionary units.

Diversity at the family level shows a sharp rise at the beginning of the Cambrian, which continues well into the Middle Cambrian. In the Middle Cambrian, a plateau was reached and several drops in diversity occurred. The main representatives of this Cambrian fauna were trilobites, inarticulate brachiopods, hyolithids, monoplacophorans, archaeocyathids, and eocrinoids (Sepkoski 1981, 1984). During the Early Ordovician, diversity increased again to reach a level about three times that of the Cambrian. Responsible for that fast and unprecedented increase in diversity were members of the Paleozoic fauna, mainly articulate brachiopods, crinoids, rugose and tabulate corals, ostracods, cephalopods,
bryozoans, asteroids, ophiuroids, and graptolites. The diversity reached by the Ordovician radiation remained almost constant through the rest of the Paleozoic, interrupted only by punctuations of extinctions and subsequent recoveries.

The Late Permian witnessed a dramatic extinction pulse, and the members of the Paleozoic Fauna lost their dominance. The Modern fauna (demosponges, bivalves, gastropods, gymnolaemate bryozoans, and malacostracan crustaceans) had its origins in the Paleozoic but its members remained a minor component up to the Permian. During the Triassic, Jurassic, and Cretaceous, members of the Modern fauna originated at a considerably faster rate than members of the Paleozoic fauna, and overall diversity increased steadily throughout the Mesozoic. The End-Cretaceous extinction appears at the family level only as a minor perturbation, and the diversity increase continues throughout the Cenozoic. By the end of the Neogene, family diversity had reached a level almost twice that of the Paleozoic.

The taxic diversity trends observed by Sepkoski were accompanied by several notable trends which relate to the structuring of the marine communities. During the Phanerozoic, the species numbers within open marine assemblages increased through time (denser “species packing”; Bambach 1977), and between the three evolutionary faunas, a significant increase in the number of feeding types and occupied substrate niches (“guilds”) is documented (Bambach 1983). In addition, the proportion of mobile taxa and of predators increased (Bambach et al. 2002). This is paralleled by changes in the spatial structure of marine benthic communities. Animals of Cambrian communities neither extended high above nor burrowed deep into the substrate, but during the mid-Paleozoic to mid-Mesozoic, many suspension feeders evolved that stood highly erect above the substrate and several tiers of epifaunal benthos developed (Ausich and Bottjer 1982; Bottjer and Ausich 1986; Signor 1990). A complex tiering as documented by the trace fossils also developed among the burrowing endobenthos although very deep burrows only became common in the latest Paleozoic.

Following the broad interest in the Phanerozoic diversity trajectories documented for marine animals, various researchers also published figures for other groups of organism (for earlier work see Valentine 1985). For insects, a synoptic curve for the number of families was published that shows a logistic increase in diversity from the Devonian to the recent. The only notable event that led to a significant decrease in the number of families seems to be the end-Permian mass extinction (Labandeira and Sepkoski 1993; Labandeira and Eble in press). Extensive data have also been assembled for tetrapods (Benton 1993). Here, the most significant outcomes are the only slight overall diversity increase from the Devonian to the Late Cretaceous and the huge increase in the number of families after the End-Cretaceous extinction (Benton 1999; Figure 16.3). Plants differ
from the various animal groups in that the family richness over the Phanerozoic follows a much smoother path, and extinctions had little effect on familial diversity (Niklas 1997).

### 16.3.2 Methodological problems

The documentation of Phanerozoic diversity patterns goes back to Phillips (1860) who used data from marine rocks in Great Britain to distinguish between Paleozoic, Mesozoic, and Cenozoic Life and showed that diversity increased throughout the Phanerozoic (see Miller 2000). Renewed interest in these large-scale patterns arose in the 1960s and 1970s, stimulated especially by the pioneering publications of Gregory (1955), Simpson (1960), and Newell (1967). The first diversity patterns published thereafter (Valentine 1969; Raup 1972, 1976a, b; Bambach 1977) showed mainly that this procedure was a very difficult task. The results were, in part, grossly dissimilar, especially with respect to the diversity increase in the Cenozoic. Although a “consensus paper” was published shortly thereafter (Sepkoski et al. 1981), discussions of methodological problems continued till date. The interpretations of Phanerozoic diversity patterns have thus fluctuated between two extremes: it might be the real picture or an artifact of databases affected by different and heavy biases.
There are problems with the taxonomic databases used which can add noise and possibly induce false signals (Signor 1985). Yet two databases at the family level compiled by Sepkoski (1982, 1992) and a team of specialists (Benton 1993) produced very similar and probably reliable results. The “pull of the recent” refers to the fact that the modern biota is much more completely sampled than fossil strata and, therefore, tends to extend the stratigraphic ranges of extant families or species that are known from some time in the Cenozoic through intervals where fossils of those taxa are missing. Yet this bias seems to be a negligible quantity (Jablonski et al. 2003).

Uneven sampling in different regions and in different periods is a fact that cannot easily be corrected for (Smith 2003). Yet it seems that the existing compendia accurately depict the large-scale global diversity trajectories (Adrain and Westrop 2000). Uneven time spans of the sampled intervals (usually stages) are a further problem. To correct for this, longer stages are subdivided, and very short ones are amalgamated (Sepkoski 1996). Taphonomic biases (differential preservation) are usually thought of as occurring randomly through the Phanerozoic, but potential biases can occur, e.g., through taxa that are only rarely preserved (e.g., in extraordinary deposits), producing a local peak in diversity for that stratigraphical interval (Sepkoski 1996). Culling of the data by removal of single occurrences (taxa that are confined to a single time interval) is the common procedure to remove this bias (Sepkoski 1996). Perhaps the most distracting factor when analyzing diversity patterns is that the sedimentary rocks available for study are not evenly dispersed through the Phanerozoic (Raup 1972, 1976b; Peters and Foote 2001; Smith 2001). Yet the diversity trajectories seem to be real and independent of the outcrop area/sediment volume (Miller 2000).

16.3.3 Expansion and equilibrium models

Although the Phanerozoic diversity trajectories and the databases used to construct them have proven to be robust, their interpretations have remained problematic. For the observed increase in familial and generic diversity, three basic models derived from population ecology can be invoked to explain the pattern (Miller 1998; Benton 2001). First, if rates of species origination and extinction were unconstrained by existing diversity and origination exceeded extinction rates, an exponential increase in taxic diversity will result, only interrupted by major extinction intervals. The second, linear model of diversity increase requires the addition of a fixed number of taxa in each unit time. This would require a constant decrease in the rate of evolution (speciation) or a regularly increasing rate of extinction, and this model is generally rejected as...
improbable (Benton 2001). The third, density dependent model assumes that after an initial slow diversity increase a rapid rise occurs, followed by a slowing rate of increase, and finally a plateau (logistic growth).

In a “decoupled logistic” simulation of the three Phanerozoic evolutionary faunas at the family level, which allowed for major mass extinctions, Sepkoski (1981, 1984) achieved a rather good fit to the observed picture. In a variation of the theme, it was proposed that the diversifications from Ordovician to recent were best matched by a series of four simple logistic curves without interaction between evolutionary faunas and only reset by mass extinctions (Courtillot and Gaudemer 1996). Exponential growth (Benton 1995) is currently no more supported for marine animals, but the exponential or nearly exponential increase in several terrestrial groups indicates that these taxa are still far away from reaching a saturation (Benton 2001).

16.3.4 Newer developments

Despite the consensus regarding the Phanerozoic diversity trajectories and the broad agreements between the different databases (Sepkoski 1982, 1992, 2002; Benton 1993), the existing global compilations have some inherent limitations. While major mass extinctions clearly affected diversity on a global scale, the trends in the intervals between these disruptions may show large differences between regions (Miller 1997, 1998, 2001). A new Paleobiology Database is currently under construction (Alroy et al. 2001; Adrain and Westrop 2003; Miller 2003) and assembles locality-specific inventories in the Phanerozoic record. This new approach will allow for a much better correction of taphonomic and sampling bias (Alroy et al. 2001; Bush et al. 2004), will yield new insights into the respective contributions of alpha, beta, and gamma diversity to the Phanerozoic taxonomic richness (Bush and Bambach 2004), and will also ultimately provide us with environment-specific information. It is likely that this will lead to a much more profound understanding of the Phanerozoic diversity patterns.

16.4 Extinctions and biotic recovery: generalities

From the conservation biologist’s point of view, the extinction of even a single species is a catastrophe. From a paleontologists view, species extinction is the normal case and more than 99% of all the species that ever inhabited earth are now extinct (Raup 1991b). Yet there is even a further, more important dimension to this: during the history of life, mass extinctions provided also
huge opportunities for taxa that hitherto played only minor roles, by removing or marginalizing incumbents (Jablonski 2001).

The same databases used in diversity studies can be used to construct plots of extinction (and also origination) intensities over time. Two major points emerge from such an analysis: peaks of high extinction intensities are separated from each other by times of lesser extinction, and overall extinction intensities decline over the phanerozoic (Sepkoski 1996; MacLeod 2003; Figure 16.4). According to Raup and Sepkoski (1982), there were 5 major and at least 18 lesser mass extinctions in the Phanerozoic, and the “big five” major extinctions (Table 16.1) are also recognized in newer studies (Hallam and Wignall 1997; MacLeod 2003; Bambach et al. 2004; Taylor 2004). A “mass extinction” is an event that was (1) nearly global, (2) removed a significant proportion of the existing species (perhaps more than 30%), (3) affected species from a broad range of ecologies, and (4) happened within a (geologically spoken) short time.

For the decline in background extinction intensity, widely disparate explanations were proposed. The change might reflect the general decrease in “volatility” between the three evolutionary faunas (Sepkoski 1981) or secular changes in the geochemistry and nutrition levels in the seas (Martin 1996). Yet it might also just be a taxonomic artifact: through the Phanerozoic, there is a trend toward more species per family/genus. It, therefore, needs more species to become extinct so that the entire family/genus becomes extinct (Taylor 2004).

An extinction event can be either abrupt, or stepped, or gradual. An abrupt or “pulse”-extinction evidently leaves a species no time to adapt or migrate, whereas this would be possible during a gradual or “press” extinction (Erwin 1996b, 2001b). Yet it has proven difficult to establish the exact disappearance of taxa, especially the rare ones. As a consequence of the imperfect fossil record, the observed last appearance of fossil taxa is always “smeared back” in time through a time interval before their actual extinction (Hallam and Wignall 1997; Taylor 2004). This “Signor–Lipps effect” (Signor and Lipps 1982) will lead to the perception of a gradual extinction pattern even if it was abrupt. The “zombie” lineage, that is the unsampled portion of a taxon’s range occurring after the final appearance of the taxon in the fossil record prior to its actual extinction (Lane et al. 2005), can be inferred at some level of probability with statistical methods (Marshall 1990).

Not even the largest mass extinctions acted in a completely random manner. Extinction selectivity can be geographical (e.g., tropical versus nontropical, terrestrial versus marine), taxonomic (different extinction rates among higher taxa, e.g., dinosaurs versus mammals, plants versus animals), or linked to trait (e.g., body size, trophic level; McKinney 1997, 2001). The selectivity patterns seen during a major extinction interval can be the same as those acting during
Figure 16.4
Extinction intensities in the Phanerozoic. Mass extinctions clearly stand out against background intensities, which decreased during the Phanerozoic. After Mac Leod 2003
pre- and postextinction times (“fair game” selectivity) or they can differ (“wanton” selectivity; Raup 1991b). Random survival with respect to trait and taxonomy was termed “field of bullet” selectivity (Raup 1991b).

Major discussions centered on the question whether mass extinctions qualify as a separate class of evolutionary mechanism and are, therefore, different from background extinctions (Jablonski 2001; Bambach et al. 2004). There is certainly a continuity of magnitude, with the “big five” and some Early Paleozoic events occupying the ranks of highest intensities (MacLeod 2003; Wang 2003) although the simple relationship between extinction intensity and mean waiting time (kill curve; Raup 1991a) is no longer accepted because continuity of cause is lacking (Wang 2003). The processes operating during mass extinctions are not the same as those acting during background extinctions (Wignall 2004). Continuity of effects is also no longer tenable as for example the end-Ordovician and end-Devonian mass extinctions both had about the same intensities, but the former had only minor consequences for the structuring of marine communities, while the latter had a profound impact on the ecosystems (Droser et al. 2000). Mass extinctions, therefore, did have a major impact on the evolution of life although most species suffered extinction during times of background extinction intensities (Taylor 2004).

Did the major mass extinctions during the Phanerozoic have a common cause? This subject was treated by several authors, and the mechanisms include impacts (as assumed, e.g., by Raup and Sepkoski 1984), sea-level changes and the spread of anoxia (Hallam and Wignall 1997), large-scale volcanisms (Courtillot 1999), and perhaps global cooling (Stanley 1988). It is not always easy to distinguish between the different mechanisms (MacLeod 2003; Table 16.2). Yet there is now overwhelming evidence that the major mass extinctions had their individual signature, and at the present state of knowledge the search for a common cause does no longer make sense.

It has been advanced already several times that the history of life follows some large-scale cyclic pattern (Fischer and Arthur 1977; Fischer 1984). Yet the notion

Simplified after Hallam and Wignall 1997.
that Phanerozoic extinction patterns show a periodicity with an interval length of 26 Myr (Raup and Sepkoski 1984) has spurred intensive debates about extinction mechanisms but has received, with increasing accuracy of the geological time scale, little support from other researchers. Currently, few paleontologists would subscribe to the idea that the mass extinctions show any periodicity, despite continued search for possible (mainly extraterrestrial) mechanisms (e.g., invisible companion of the sun, “nemesis,” inducing a comet shower when passing through Oort Cloud; an eccentrical “planet X” doing the same job; the passing of our solar system through the spiral arms of our galaxy, again perturbing bolides in the Oort cloud; movement of the solar system through the galactic plane; Sepkoski 1990).

It comes as a major surprise that a new study indicates again that the diversity of life on earth followed some cyclic pattern, this time with a 62 Ma periodicity (Rohde and Muller 2005). Yet this pattern has yet to be scrutinized, and it might simply be the inevitable outcome of the applied methods.

The phase after a mass extinction usually shows a peculiar fauna/flora that change gradually during the time following the extinction. Some terminology has proven to be helpful for the characterization of these intervals (Kauffman and Erwin 1995; Figure 16.5). The extinction phase is the time where most of the affected taxa had their last appearance. This is followed by the survival phase where some groups not severely affected by the extinction (holdover taxa) already began to diversify. During the survival phase, there is usually a small number of opportunistic taxa that could temporarily spread at the expense of the other fauna.

After MacLeod 1998.
Lazarus taxa (Jablonski 1986) are those that disappear, probably by becoming very rare (and not retreating to refugia; Wignall and Hallam 1999) during the survival phase only to later reappear during the recovery phase when new ecosystems are being established, while Elvis taxa (Erwin and Droser 1993) were those that entered newly the fossil record but mimicked the shape of extinct taxa. The new communities were largely shaped by progenitor taxa, the most prolific during the recovery phase (Kauffman and Erwin 1995; Hallam and Wignall 1997).

It was long recognized that reefs showed, after mass extinctions, a prolonged recovery interval. This “reef gap” (Hallam and Wignall 1997; Stanley 2001; Jablonski 2003), which is evident after all of the “big five” and also after the extinction event after the end of the Lower Cambrian (extinction of the Archeocytha; Copper 1988), probably reflects the longer time it needs to reassemble complex ecosystems (Jablonski 2003).

16.5 Selected case studies

16.5.1 The Cambrian radiation and its prelude

The tracking of the appearance and early diversification of the animals in the fossil record (Figure 16.6) is at present one of the fields in paleontology where extremely rapid progress is made. New input came especially from molecular...
Figure 16.6
Major events during the latest Neoproterozoic and the Cambrian. After Erwin 2001
systematics (Adoutte et al. 2000; Giribet 2002; Pennisi 2003; Halanych 2004; Peterson et al. 2004) and through precise, absolute dating of fossiliferous Late Neoproterozoic and Early Cambrian sections, which allowed the establishment of a reliable chronostratigraphic framework (Martin et al. 2000; Knoll et al. 2004).

Possibly the oldest metazoans are ring- and disk-shaped impressions from the Mackenzie mountains in northwestern Canada, dated as 610–600 Ma and hence of the same age as the terminal Marinoan–Varanger glaciation. This soft-bodied fauna was called Ediacara assemblage I and represents perhaps cnidarian grade animals (Erwin 2001a). Considerably more diverse but younger Ediacaran assemblages are known from a number of localities around the world (Bottjer 2002; Brasier and Antcliffe 2004). The fauna of these Ediacaran assemblages II and III consists exclusively of soft-bodied forms. The body wall of these organisms must have been quite rigid as is evident from the taphonomic behavior of the Ediacaran biota. They are preserved, mostly intact, as impressions at the base of event beds (storm layers, turbidites) that quickly buried them (Erwin 2001a; Bottjer 2002).

Most of the forms are flattened, segmented or quilted, and some of them attain considerable sizes (Narbonne and Gehling 2003). Classification of these organisms has been highly controversial. Traditionally, the various species were assigned to extant groups like medusae, sea pens, polychaete worms, and stem group echinoderms (Wade 1972a, b; Glaessner 1983, 1984; Jenkins 1992), with most of them belonging to cnidarians. Today most researchers believe that the majority of the enigmatic Ediacaran organisms represent “lost constructions” (Seilacher 1989, 1992; Buss and Seilacher 1994; Narbonne 2004, 2005). With the exception of the 555-Ma-old Kimberella, which is now considered to be an ancestral mollusk (Fedonkin and Waggoner 1997; but see Dzik 2003; Budd and Jensen 2004) and therefore the oldest body fossil of a bilaterian, Ediacaran organisms seem to lack a mouth and a digestive tract. Most were immobile, many of them recliners but some also mud-stickers (Seilacher 1999). Nutrient uptake was either through the body surface, or these organisms lived in symbiosis with photosynthetic/chemosynthetic protists or bacteria (McMenamin and McMenamin 1990; Narbonne 2005). Although sponges and cnidarians were most probably also present, predators were notably absent. The immobile organisms thus lived in a “Garden of Ediacara” (McMenamin and McMenamin 1990). The sediment surface was frequently sealed by microbial mats that were not disrupted by larger burrowing animals. Traces including some radular scratch marks are small and rare and are proof of the presence of bilaterians. Claims for evidence of bilaterians earlier than the Ediacaran assemblages (e.g., traces from 1200-Ma rocks in India; Seilacher et al. 1998) are published with some frequency but these are not accepted (Erwin and Davidson 2002).
An exciting new window into Late-Proterozoic life recently opened with the discovery of 600–580-Ma-old fossiliferous phosphorites at Doushantuo, southern China (Xiao et al. 1998). In addition to various algae, microscopic metazoan embryos preserved at the cellular level were found. The affinities of these early cleavage stages are unclear but they might possibly be of bilaterian origin (Knoll and Carroll 1999; Valentine et al. 1999). Newer claims for small bilaterian animals (Vernanimalcula) with preserved coelom and digestive tract from the same locality (Chen et al. 2004) are not widely accepted (Stokstad 2004). The Ediacaran biota largely went extinct at the Precambrian–Cambrian boundary (Brasier and Antcliffe 2004) with perhaps a few survivors into the Middle Cambrian (Conway-Morris 1993).

The base of the Cambrian, which is now dated at 542 Ma (Gradstein and Ogg 2004; Ogg 2004), marks the beginning of an interval which is the most remarkable in the history of life. During the Early Cambrian, a wide range of skeleton-bearing animals made their debut, and within only 20 Myr, almost all phyla with preservable hard parts entered the fossil record (sponges already earlier, bryozoans in the Ordovician, but might have exclusively soft-bodied representatives in Cambrian; Valentine 2002, 2004). This apparent explosion of animal bauplans, which had already puzzled Darwin, is still one of the greatest enigmas, although it has become clear in the last few years that there was a prelude of perhaps tens of million years (Lieberman 2003) seen both among traces and in the shelly fossils, but no lengthy time gap between the Ediacaran assemblages and the lowermost Cambrian (Knoll and Carroll 1999; Erwin 2001; Valentine 2002).

At first we see an increasing size and complexity of burrows/traces across the Precambrian–Cambrian boundary and then an ever increasing diversity during the Early Cambrian (Crimes 1992, 2001; Droser and Li 2001). In parallel, there was a huge diversification in the so-called “small shelly fossils” (Rozanov and Zhuravlev 1992; Conway-Morris 1998, 2001; Grotzinger et al. 2000). The appearance of new animal phyla and other higher taxa was concentrated in an interval between the latest Manykayan and the Atdabanian spanning perhaps 10 Myr, and this interval is called the “Cambrian explosion” and saw even the appearance of phyla that shortly thereafter became extinct (Dzik 1993; Valentine et al. 1999; Conway Morris 2000). By the end of the Cambrian explosion, the phylum-level diversity among marine animals had surpassed that seen in today’s oceans! During this interval, biomineralization was acquired by a multitude of organisms, including mollusks, brachiopods, echinoderms, and chordates (see Lowenstam and Weiner 1989; Bengtson 1994; Zhuravlev and Riding 2001 for an overview). Complex arthropods, like trilobites, enter the fossil record during the Atdabanian stage, and by the Middle Cambrian, a plateau in diversity was reached.
Our picture of the Cambrian explosion is facilitated by several wonderful, exceptional fossiliferous settings (Fossilagerstaetten), including the Early Cambrian localities of Chengjiang (China; Xian-guang et al. 2004) and Sirius Passet (Greenland; Conway Morris 1998), and the most famous Middle Cambrian Burgess Shale (Canada; Briggs et al. 1994). Several very important questions surround debates about the Cambrian explosion. (1) Is it real or just an artifact of the imperfect fossil record? (2) Does the origin of metazoan phyla substantially predate their appearance in the fossil record? (3) If the event was real, what was the triggering mechanism?

The current consensus is that the Cambrian explosion was indeed real and happened in just a 10-Ma interval between the late Manykayan and the Atdabanian (Valentine et al. 1999; Conway Morris 2000; Erwin 2001; Valentine 2002, 2004). Yet the Cambrian explosion does not record the initial split of the metazoans but rather the diversification of the three fundamental metazoan groups into the crown groups and the modern phyla (Douzery et al. 2004; Peterson et al. 2004; Valentine 2004). Ecologically, the Cambrian revolution led to a massive restructuring of the marine benthos. An increasing percentage of animals were burrowers that fed on nutrients within the sediment, or that constructed tubes. As a consequence of the increasing bioturbation (Droser and Li 2001), the sediment became destabilized and the superficial microbial mats were lost. This “agronomic revolution” (Seilacher 1999) led to an uppermost mixed layer, and besides the Ediacara organisms, many immobile recliners and mudstickers like the helicoplacoid echinoderms went extinct (Bottjer et al. 2000; Dornbos and Bottjer 2000; Dornbos et al. 2005).

With respect to the triggering mechanism(s) of the Cambrian explosion, our explanations are still very much speculative. The synchronous radiation of many disparate phyla has led strong support to the idea that there must have been an environmental trigger (physical or biological; Valentine 2002, 2004). Among the hypotheses that are advanced are a significant increase in oxygen in the oceans but this hypothesis is at odds with observations that oxygen reached sufficient levels to sustain metazoan life long before the Early Cambrian (Knoll 1996; but see Hedges 2004). The amalgamation of continental plates followed by a transgression was also cited as a possible trigger (Brasier and Lindsay 2001). There were certainly dramatic changes in the chemistry of the oceans during the latest Precambrian as is evident from isotope studies. Increased nutrient levels in the oceans might have facilitated the radiation (Brasier 1992). Furthermore, a major increase in Ca\(^{2+}\) levels during the earliest Cambrian is documented which certainly facilitated biomineralization (Brennan et al. 2004). One of the most commonly involved biological explanations of the radiation is that skeletons developed in a number of groups as an answer to increasing predator pressure.
(Conway Morris 2001; see also Stanley 1973) and perhaps also the evolution of animal vision (Parker 2003), thereby allowing new adaptational opportunities. The Cambrian saw indeed the appearance of many carnivores and scavengers, and this trophic group accounted for up to 25% of the species in the Middle Cambrian (Burzin et al. 2001). Furthermore, the development of planktonic habits in a range of groups greatly increased the complexity of food webs and was also responsible for animal diversification (Butterfield 2001).

Many paleontologists were deeply impressed by the wide variety of different body plans, especially among arthropods, that appeared during the Cambrian explosion. The number of taxa known from the famous Cambrian Lagerstätten that do not fit easily into any classification scheme based on living animals is extraordinary. It was claimed that morphological disparity among Cambrian animals was even higher than that seen today (Gould 1989, 1991) and some extraordinary evolutionary mechanisms acted during the Cambrian explosion. Measuring morphological disparity is a relatively new field and seems to be a promising avenue to complement measures of taxonomic diversity (Foote 1997; Wills 2001). Detailed analyses of arthropods showed that disparity among the Cambrian forms was not higher than among modern species and the level of appendage specialisation is much higher today than in the Cambrian (Briggs et al. 1992; Wills et al. 1994). Special evolutionary processes do, therefore, not seem to have operated during the Cambrian explosion. Yet it remains nevertheless remarkable how early and synchronous the multitude of higher animal taxa appeared in the fossil record.

16.5.2 The Ordovician radiation

During the Ordovician, taxic diversity at the family and generic level reached a new maximum which was three to four times that of the Late Cambrian (Miller 1997, 2001). While during the Cambrian explosion numerous phyla and classes representing basic body plans originated, the Ordovician radiation was manifested by an unprecedented burst of diversification at lower taxonomic levels. According to the global picture of Sepkoski (1979, 1997), the Cambrian fauna (e.g., the trilobites) declined while the articulated brachiopods, the crinoids, stenolemate bryozoans, and other members of the Paleozoic fauna showed a sharp increase. To a lesser degree, members of the modern fauna like gastropods and bivalves also diversified (Miller 2001).

The almost exponential increase in diversity was much more rapid during the Ordovician than at any other time of the Phanerozoic (Sepkoski 1997; Webby 2004). This global diversity increase seems to have been the combined result of an
increase in $\alpha$- (within community), $\beta$- (between communities), and $\gamma$-diversity (biogeographic differentiation between faunal provinces; Webby 2004). New ecological guilds appeared, and the spatial organization of the benthic communities became considerably more complex (Bottjer and Ausich 1986; Droser and Bottjer 1989, 1993). The Ordovician was also a time of marked shift in the reef biota. Whereas Early Ordovician reefs were mainly built of microbial mats and stromatolites, large metazoan-dominated framework reefs had developed and spread on all continents by the end of the Ordovician (Webby 2004). The diversification and spread of metazoan reefs was accompanied by an increase in bioeroding organisms colonizing reefs and hardgrounds ("bioerosion revolution"; Wilson and Palmer 2001).

Yet when the global picture is dissected at finer taxonomic, geographic, and environmental levels, some surprising results emerge (Miller 1997). The diversification seemed not to follow a global trajectory but to respond much more to local conditions in paleogeography, sedimentary environment, and orogenetic activity. The general decline of Sepkoski’s Cambrian fauna is an oversimplification. The “smooth” global diversity increase during the Ordovician is, thus, the aggregate record of many regional patterns which were for the most part abrupt (Miller 1997, 2001, 2004; Westrop and Adrain 1998).

Not a single reason but rather a combination of paleogeographic, sedimentologic, geochemical, and perhaps intrinsic factors seems to be responsible for the diversity increase during the Ordovician. The paleogeographic situation was one of a highly fractured continental crust with many small continents. Together with a very high sea-level stand and increasing nutrient inputs, this provided extensive shelf areas in many different parts of the world and, therefore, a multitude of colonizable areas (Miller 1997). There is also a good correlation between diversity increase and orogenic activity. Throughout the Ordovician and the remainder of the Paleozoic, there was clearly a trend toward increased primary productivity and away from oligotrophic conditions (Martin 1996).

16.5.3 The Late Ordovician mass extinction

With 26% of the marine families, up to 60% of the genera and an estimated 85% of all the species becoming extinct, the Late-Ordovician mass extinction was one of the most severe extinction episodes in the Phanerozoic, surpassed in its magnitude only by the end-Permian mass extinction. Its extent was global, and it affected nearly all benthic and pelagic groups (Hallam and Wignall 1997; Brenchley 2001; Sheehan 2001b; Figure 16.7).
Figure 16.7 Extinction patterns during the Late Ordovician mass extinction. Modified after Hallam & Wignall 1997.
During the Late Ordovician, greenhouse conditions prevailed but during the latest stage (Hirnantian), a short glaciation of approximately 0.5-Ma duration occurred (Brenchley 2001; Sheehan and Harris 2004). The glaciation probably started when Late Ordovician orogenic activities led to extensive exposure and weathering of silicate terrains and, therefore, CO$_2$ consumption. Under falling CO$_2$ levels, ice sheets started to grow and albedo feedback led to an extensive Gondwana glaciation. The ice cover in turn inhibited silicate weathering, and CO$_2$ levels rose again. After a threshold was reached, greenhouse conditions returned and the ice caps melted quickly (Kump et al. 1999). It is now well documented that the mass extinction during the Late Ordovician was a two-phase event and the first extinction pulse at the base of the Hirnantian *extraordinarius* zone corresponded to the initiation of the Gondwana glaciation and the second pulse in the first third of the *persculptus* zone to the rapid decay of the polar ice cap.

During the first extinction event, various groups suffered heavy losses. Thereafter, an impoverished and remarkably cosmopolitan benthic fauna was present on most shelves from high latitudes to the tropics. This so-called *Hirnantia* fauna can be regarded as a cool-adapted, opportunistic community that spread after the extinction removed the hitherto dominant species (Brenchley 2001; Sheehan 2001b; Jia-Yu et al. 2002). Primary productivity was obviously much reduced during the Hirnantian.

The second extinction phase was again sharp and hit most of the groups that suffered already during the first extinction pulse. It eliminated much of the benthic *Hirnantia* fauna (Hallam and Wignall 1997), but the recovery interval did not last very long. It is most surprising that the faunal turnover during the Late Ordovician mass extinction was accompanied by very little ecological changes, and the structure of Silurian communities is remarkably similar to those of the Late Ordovician (Droser et al. 2000; Bottjer et al. 2001; Sheehan 2001b).

The causes of the two extinction pulses were certainly linked to the rapid onset and the later abrupt termination of the Gondwana glaciation during an otherwise warm climatic mode (Fortey and Cocks 2005). Global cooling of the oceans of perhaps as much as 8°C together with a loss of benthic habitat due to regression might have, in part, been responsible for the first extinction (Berry and Boucot 1973; Brenchley et al. 1994; Armstrong 1996). Yet pelagic forms also suffered heavy losses, and changing circulation patterns in the oceans were probably crucial (Hallam and Wignall 1997). The widespread deep anoxic waters, the extensive dysoxic zone, and the nutrient-rich surface waters vanished during the onset of the glaciation when cold, deep water led to intensified ocean circulation. During the second pulse, the termination of cold, deep water production led again to widespread stratified oceans with
anoxic deep and intermediate dysoxic waters. Black shales accumulated again, and the transgressing dysoxic waters eliminated most of the benthic *Hirnantia* fauna and other benthic organisms not resistant to oxygen-poor conditions (Hallam and Wignall 1997).

### 16.5.4 The Late Devonian mass extinction

No less than 11 global extinction events were identified in the Givetian through Famennian stages (Walliser 1996) but only the lower and upper Kellwasser events (Frasnian–Famennian boundary) and the Hangenberg event (uppermost Famennian) amount to a magnitude that deserve the name mass extinction (Hallam and Wignall 1997). Yet the stress imposed by the many smaller events, especially the earlier Thaganic event in the uppermost Givetian, was probably crucial for the overall extinction patterns in maintaining a high level of environmental stress throughout the Late Devonian.

At least 70% and perhaps as many as 82% of the marine species became extinct during this time period (McGhee 1996, 2001; [Figure 16.8](#)). Among the groups that were most severely hit were the reef builders (Fagerstrom 1994; Hallam and Wignall 1997; Copper and Scotese 2003), but other benthic organisms, especially tropical families, also suffered heavy losses during both major crises. The toll was no less severe in planktonic and nektonic groups, and the armored agnathans and the placoderms went completely extinct (Hallam and Wignall 1997).

Quite important for the elucidation of the possible causes of the Late Devonian mass extinctions is that their selectivity differed between the different events. The Taghanic event affected mainly benthic taxa from low-latitude, shallow-water environments (Hallam and Wignall 1997). The Kellwasser events also affected mainly warm-water species as well as planktonic and pelagic groups. During the Hangenberg crisis, it was the planktonic and nektonic groups that were most severely hit while the benthic groups showed a better survival than at the Frasnian–Famennian boundary.

The extinction patterns in the Late Devonian were highly complex and a result of several mechanisms spread over a time period of more than 10 Ma, with the most severe perturbations concentrated at the Frasnian–Famennian boundary and in the latest Famennian (Sandberg et al. 2002). Global cooling of the oceans (Copper 1986) was certainly one of the main causes of the extinctions (McGhee 1996, 2001), although the Gondwana glaciation only started in the Late Famennian (Caputo 1985; Algeo and Scheckler 1998). Yet beside the cooling, frequent sea-level changes including both eustatic rises associated with spreading anoxic waters and
Figure 16.8
Extinction patterns during the Late Devonian mass extinction. Modified after Hallam & Wignall 1997
regressions responsible for habitat loss are also well documented (Sandberg et al. 2002). The Late Devonian was also a time of increased impact frequency. Well-dated craters, shocked minerals, and microtectites as well as iridium anomalies are known from different continents (McGhee 1996, 2001; Sandberg et al. 2002), and these impacts certainly increased the environmental stress.

### 16.5.5 Devonian to Carboniferous expansion of land flora

The earliest vascular land plants are known from Late Silurian strata. Colonization of the terrestrial environment, at least in moist lowlands, obviously happened rather quickly, and within only 45 Ma, all major land-plant lineages and organizational grades (except for flowering plants) developed (Niklas 1997, 2004; Willis and McElwain 2002). All the morphological adaptations including a protective outer covering (waxy cuticula) against desiccation, stomata to allow gas diffusion, specialized tissues for the transport of liquids, and rigid cell walls (Chaloner 2003) developed in the Devonian, although accompanied only by a modest diversification at the species level (Niklas 1997; Willis and McElwain 2002). By the end of the Devonian, the terrestrial environment saw the first globally distributed forests with large trees (Chaloner 2003). This resulted in a huge increase in biomass that culminated in the Late Carboniferous. Much of this organic material was not decomposed and recycled but instead buried in moist anoxic soils (acidic swamps; Chaloner 2003).

This expansion of the land flora had a profound impact on earth’s environmental conditions. Most important was the removal of large quantities of CO₂ from the atmosphere through photosynthetic carbon fixation. The most widely accepted models for Phanerozoic CO₂ show a sharp decrease from about 15 times the present level (15 PAL) at the beginning of the Devonian to 10 PAL at the Devonian–Carboniferous boundary and a further decrease to less than 2 PAL in the Late Carboniferous (Berner 1998; Royer et al. 2000). With the massive drop in available CO₂, a high stomatal density became crucial, and the laminate leaf rapidly became widespread (Beerling et al. 2001) although at the cost of higher water loss through transpiration (Chaloner 2003).

During the Devonian, the increase in the sizes of the trees was accompanied by increasing depth and complexity of the roots (Algeo and Scheckler 1998). This in turn accelerated silicate weathering and led to a further drawdown of carbon as bicarbonate into rivers and ultimately into the seas (Kump et al. 2004). The most obvious consequence of this huge decrease in atmospheric CO₂ was the onset of the Gondwana glaciation. In the Late Devonian, the southern continents were
assembled near the South Pole, and the first polar ice caps developed in the latest Devonian. However, the main phase of the Late-Paleozoic glaciation started in the Early Carboniferous. With its duration of more than 80 Ma (Crowley and North 1991; Frakes et al. 1992), well into the Permian, this glaciation was by far the longest and also the latitudinally most extensive of the Phanerozoic ice ages. Yet it was not associated with any major mass extinction pulse.

The very high productivity of the plants during the Devonian and Carboniferous also led to a significant increase in atmospheric oxygen, with 30–38% O$_2$ in the Late Carboniferous (Berner 1999; Berner et al. 2003; Bergman et al. 2004). This seems to have had yet another impact on life. With increasing oxygen partial pressure, the diffusive flux is increased considerably, allowing the evolution of gigantic sizes (Graham et al. 1995; Dudley 1998), most notably among terrestrial arthropods and amphibians (Briggs 1985; Graham et al. 1995). For the giant flying insects, the higher density of the atmosphere might also have played a role (Dudley 1998, 2000).

16.5.6 The end-Permian mass extinction and subsequent recovery

The mass extinction at the end of the Permian was recognized already for a long time as the most severe of all the Phanerozoic perturbations (Phillips 1860). The radical faunal change associated with this biotic crisis was the reason to distinguish between the Paleozoic below and the Mesozoic above. More than 50% of marine and terrestrial families went extinct and an estimated 80–96% of all the species. Until recently (Erwin 1990, 1993), the end-Permian mass extinction was seen as a protracted crisis, which lasted for approximately 10 Ma. Newer research has shown that there were actually two discrete events (Figure 16.9). The first occurred in the latest Guadalupian (terminal Middle Permian) and affected only some groups in a more gradual way (Hallam and Wignall 1997). The event at the very end of the Permian was apparently of quite short duration (probably less than 0.1 Ma; Erwin et al. 2002). It is this interval that has been called “the mother of all extinctions,” “the great dying,” or the “Paleozoic nemesis” (Erwin 1996; Benton 2003). This massive crisis affected all groups of organisms, both in the seas and on land (Benton and Twitchett 2003).

In the Middle Permian, the seas were teeming with life and many different faunal provinces can be distinguished. Highly diverse stromatoporoid-coral reefs were widely distributed. On soft- and hard-bottoms, rich communities dominated by brachiopods and echinoderms flourished, and in the water-column, numerous ammonoids and various fish groups had attained a high diversity.
Figure 16.9
Extinction patterns during the end-Permian mass extinction. Modified after Hallam & Wignall 1997
On land, insects had reached their highest diversity in the Paleozoic and tetrapod communities were probably as complex as modern mammal communities (Benton 2003). Plants were also highly diverse and distributed in different biogeographical provinces.

During the first extinction event, which occurred at the end of the Middle Permian (Guadalupian), some groups were affected both on land and in the seas but none became entirely extinct (Hallam and Wignall 1997). The reasons for this first extinction pulse are not well understood, but global cooling has been cited as the underlying cause (Stanley 1988; Hallam and Wignall 1997).

The second and by far the more severe extinction pulse near the Permian–Triassic (P–Tr) boundary affected all the taxonomic and ecologic groups, both in the seas and in the terrestrial environment. Among the larger groups that completely went extinct in the seas were the rugose and tabulate corals, fenestrate bryozoans, and orthid brachiopods. On land, glossopterids and cordaitales were suddenly replaced by a low-diversity conifer-lycopod-fern assemblage with little provinciality. Palynological samples from immediately above the P–Tr boundary are dominated by fungal spores which normally account for only a small proportion of the pollen and spores. This “fungal spike” (Eshet et al. 1995; Visscher et al. 1996), similar in its magnitude to the “fern spike” at the Cretaceous–Tertiary boundary, might indicate vast areas of rotting plants which were decomposed by fungi (Hallam and Wignall 1997; Benton and Twitchett 2003). A wide range of tetrapods, among them the hitherto dominant pareiasaurs, went abruptly extinct, and the Early Triassic vertebrate faunas were completely dominated by the single genus *Lystrosaurus* (Hallam and Wignall 1997; Benton and Twitchett 2003; Ward et al. 2005). Both remarkable were the magnitude (up to an estimated 96% of the marine species) and the extraordinary long recovery interval. It took almost 100 Ma for family diversity to reach preextinction levels and almost 10 Ma for complex ecosystems like reefs to become established again (Benton and Twitchett 2003). The first communities that appeared during the recovery interval are composed of a remarkably cosmopolitan, opportunistic fauna of thin-shelled bivalves (e.g., *Claraia*) and lingulid brachiopods (Hallam and Wignall 1997). Burrowing organisms were almost completely absent, and disaster taxa like stromatolites became locally abundant (Schubert and Bottjer 1992). Lazarus taxa were especially common among the gastropods, and most of them were small (“Lilliput”-effect; Twitchett 2006). The long-term consequences for seafloor communities were the replacement of the hitherto dominant epibenthic sessile suspension feeders by a vagile, epi- and endobenthic, mollusk-dominated fauna (Hallam and Wignall 1997). The recovery interval after the end-Permian mass extinction is much longer than for any other extinction event and indicates that the ecosystems were almost completely devastated and
severe environmental perturbations continued through the Lower Triassic (Twitchett 1999; Payne et al. 2004).

The scenario for this mass extinction and its likely causes have received much attention in the last decade. All the evidence indicates that the mass extinction occurred during a phase of marine transgression and severe global warming. The catastrophe probably started with the release of huge amounts of CO2 into the atmosphere, first through volcanic eruptions in South China (Emeishan flood basalt province; Lo et al. 2002) and perhaps also through coal oxidation (Hallam and Wignall 1997), later through vast eruptions in Siberia (Siberian traps; Courtillot 1999; Benton and Twitchett 2003; but see Wignall 2001a). This led to global warming and in the seas to decreased ocean circulation and oxygen depletion (Wignall and Twitchett 1996). With further increasing CO2 levels, methane hydrates began to melt and released large quantities of methane, which first acted as greenhouse gas and later was oxidized to CO2. Through this positive feedback, a “runaway greenhouse” developed, which went out of control after some threshold was reached (Benton and Twitchett 2003). The seas flooding the shelves became anoxic, perhaps even sulfidic (Kump et al. 2005), and killed most of the benthic and pelagic organisms. On land, the vegetation suffered a severe deterioration with equally devastating consequences for the animals, which also experienced hypoxic stress (Huey and Ward 2005).

Inevitably, many additional or alternative explanations have been presented. A major global regression during the terminal Permian was long a popular explanation for the extinction but this is no longer tenable. There was clearly a transgression during the P–Tr boundary interval (Hallam and Wignall 1997). Darkening and global cooling with a collapse in photosynthesis was also proposed as extinction cause (Campbell et al. 1992), but all the evidence points to global warming at the end of the Permian. Older suggestions include brackish oceans and an increase in cosmic radiation. The claim for evidence of an impact is relatively recent (Becker et al. 2001, 2004). However, the impact hypothesis is now generally considered invalid (Erwin 2003). The end-Permian mass extinction thus seems truly “home-made” (Benton and Twitchett 2003).

16.5.7 End-Triassic extinction

The extinction at the end of the Triassic (Figure 16.10) is recognized as one of the “big five” Phanerozoic mass extinctions but documenting the exact timing and the causes of biotic overturn has proven difficult. There was a widespread regression at the end of the Triassic and marine sections which span the Triassic–Jurassic (Tr–J) boundary are known from only a few localities (Hallam and Wignall 1997).
Many marine groups suffered a dramatic and sudden decrease in diversity at the end of the Rhaetian, but others witnessed a major reduction in diversity already during the Norian and earlier Rhaetian (Teichert 1990; Hallam and Wignall 1997; Hallam 2002; Tanner et al. 2004). Terrestrial plant extinction intensities seem to have been concentrated at the Tr–J boundary, and the boundary layer contains an unusually high fern spores/pollen ratio (Olsen et al. 1990, 2002).

Among terrestrial vertebrates, a major extinction is undisputed, but the main turnover occurred near the Carnian–Norian boundary (Benton 1994; Lucas 1994). Instead of an abrupt extinction, there is, thus, a rather complex pattern, and no single catastrophe seems to be responsible for the terminal Triassic turnover. Global climate changes could explain the decline in terrestrial diversity during the
Late Triassic (Tanner et al. 2004). Habitat loss and changing substrates associated with the regression in the latest Rhaetian, followed shortly thereafter by a transgression at the Rhaetian–Hettangian boundary, might have in part been responsible for the observed pattern in the marine realm. Contrary to earlier beliefs (Hallam and Wignall 1997), the transgression at the Tr–J boundary does not seem to have been accompanied by widespread anoxic waters on the shelves (Hallam and Wignall 1999; Tanner et al. 2004), but such an event might have occurred earlier, during the Norian–Rhaetian transition (Tanner et al. 2004). Extensive and widespread volcanism related to the rifting of Pangea around the North Atlantic at the Tr–J boundary was only recently recognized. The outgassing of CO₂ from this Central Atlantic Magmatic Province (CAMP; Marzoli et al. 1999) might have had truly deleterious effects like enhanced seasonal fluctuations and an increase in the number and severity of hot days as well as a decrease in ocean water oxygenation (Huynh and Poulsen 2004). An impact scenario (Olsen et al. 2002) is largely dismissed today because the extinction pattern is not a sudden, catastrophic one, various impact craters have been dated as Carnian–Norian, and claims for significant iridium anomalies and shocked quartz could not be verified (Hallam 2002; Tanner et al. 2004).

16.5.8 Mesozoic marine revolution

The term “Mesozoic marine revolution” (MMR) (Vermeij 1977) refers to the idea that during the Mesozoic a profound reorganization in the marine communities led to a significant increase in predation pressure and prey species developed various adaptations (thicker shells, spines, behavioral responses) to cope with this increasing pressure (“arms race” or “escalation”; Vermeij 1987; Harper 2003, 2006). It is undisputed that during the Mesozoic, especially during the Jurassic and Cretaceous, the number of marine grazers as well as durophagous and drilling predators increased considerably (Vermeij 1977, 1987).

This rise in predatory groups was accompanied by profound changes in marine benthic communities. The epifaunal guilds like stalked crinoids and brachiopods, which were so characteristic of Paleozoic communities, vanished from shallow-shelf environments, and those epifaunal species that did persist in shallow water do show a high frequency of regeneration and, therefore, predator attacks (Vermeij 1987). A marked shift toward infaunal life modes is documented in post-Paleozoic echinoids, gastropods, and especially bivalves (Stanley 1977; Thayer 1983; Vermeij 1987), although this shift predates the appearance of most shell crushers (Harper 2003). The most conspicuous changes during the MMR occurred in shell architecture. Overall, the shells became sturdier, more highly armored, and
developed spines, ribs, and thickened and narrowed apertures (Vermeij 1977, 1987; Ward 1981, 1983). At least among gastropods, shell-repair scars became much more frequent, pointing again to increasing predation pressure.

According to Vermeij (1987), it was the biological interactions (competition, predator–prey relations) that led to the evolution of these long-term trends. Yet the biological evolution toward increasing predator-resistant shells might also have been facilitated by changes in the abiotic conditions. Extensive volcanism, which in turn augmented water temperature, high nutrient levels, and a high sea-level stand all facilitated the production of energetically expensive massive shells (Vermeij 1995) and perhaps as well the general increase in diversity and increasing “fleshyness” of the fauna throughout the Mesozo- and Cenozoic (Bambach 1993). Secular changes in oceanographic and geochemical conditions most certainly spurred other important changes in the marine biota during middle and late Mesozoic times. Planktonic foraminifers appeared in the Middle Jurassic and became numerically important during the Cretaceous. Coccoliths are known since the Triassic, but they became widespread and abundant during the Late Jurassic and the Cretaceous. This rise in planktonic calcifiers was perhaps facilitated by the intensified bioturbation of the seafloor which effectively recycled nutrients (Kelley and Hansen 2001) but had in turn tremendous effects on the carbon cycle and the CaCO₃ saturation of the oceans (Ridgwell 2005).

16.5.9 End-Cretaceous mass extinction

This is certainly the most widely known and probably also the best investigated of the major mass extinctions, simply because the popular (nonavian) dinosaurs disappeared at the Cretaceous–Tertiary (K–T) boundary. Yet it is, with a 16% loss of the families, a 47% loss of the genera, and an estimated loss of at least 70% of the species in the marine realm, the least severe among the five major mass extinctions in earth history (Jablonski 1994; Hallam and Wignall 1997; Figure 16.11). Some marine groups disappeared completely at the end of the Cretaceous (e.g., the large marine reptiles), others suffered heavy losses (especially planktonic groups), but there were also groups that exhibited little or no reduction over the last Cretaceous to the lowermost Paleogene (MacLeod et al. 1997; Norris 2001).

On land, plants suffered evidently little long-term reduction (Niklas et al. 1983; Niklas 1997; Willis and McElwain 2002), but in many sections a short proliferation of ferns at the expense of angiosperms (“fern-spike”) is documented. Among the tetrapods, amphibians, turtles, crocodilians, and eutherian mammals were largely unaffected by the K–T boundary event, whereas lizards and marsupials suffered heavy losses (Archibald and Fastovsky 2004). For the

ornithischians and the (nonavian) saurischians, this event was of course the end of a long era. Land-dwelling species were more severely hit than freshwater inhabitants, endothermic tetrapods (including ornithischians and saurischians) more than ectothermic, and larger more than smaller species (Archibald 1996; Archibald and Fastovsky 2004).

Evidence for both a gradual decline in dinosaur species richness as well as for a catastrophic and (geologically spoken) instantaneous extinction of the dinosaurs was presented (Hurlbert and Archibald 1995; Archibald and Fastovsky 2004), but the most recent data indicate again that the dinosaurs went abruptly extinct during the time of their highest diversity (Fastovsky et al. 2004). The picture is equally complicated in marine exposures in which again evidence for both a gradual as well as a sudden extinction was presented (see MacLeod et al. 1997). Yet resampling of formerly investigated sections extended taxonomic ranges upward and the reported gradual decline of many groups might well be a consequence of the Signor–Lipps effect (Ward 1990).

Among the possible causes for the K–T mass extinction that are still considered today are volcanism, climatic fluctuations, and marine regression, and an asteroid impact (Benton 1990). There is indeed overwhelming evidence that the earth was hit by a major asteroid perhaps 10 km in diameter that had a devastating impact on earth’s life. This evidence includes molten sediment particles (glass spherules), shocked quartz grains, and a worldwide recognized enrichment in iridium in K–T boundary layers (Alvarez et al. 1980, 1995). The impact hypothesis received further support with the discovery of a 65-Ma old impact crater (Chicxulub) on the Yucatan peninsula, Mexico (Hildebrand et al. 1990). Yet it has also been demonstrated that the latest Cretaceous was a time of major climatic fluctuations (Skelton 2003) and the pronounced marine regression at the end of the Maastrichtian was recognized already a long time ago. In addition, intensive volcanism, which spanned less than 2 Ma over the K–T boundary, is documented from the so-called “Deccan Traps” (Courtillot 1990, 1999). These represent immense outpourings of lava in what is today India and must have had a profound impact on the biosphere (Kelley 2003).

Currently there are two schools of thought to explain the K–T mass extinction. According to the gradualistic, multiple causes–scenario (Archibald 1996; see also Archibald and Fastovsky 2004), the climatic fluctuations and the marine regression near the end of the Cretaceous changed profoundly the available habitats in both the terrestrial and marine environments. This biotic stress led to a gradual decline in the dinosaurs and other terrestrial vertebrates. Likewise, the regression also imposed a major stress on the marine animals by reducing the available shelf environments. Further stress was imposed by the Deccan Trap volcanism that erupted large amounts of dust into the atmosphere, with general
cooling of the globe, drying of many terrestrial ecosystems, and slowing of the photosynthetic activity as the most likely consequences. The asteroid impact at the K–T boundary with its devastating environmental consequences is not disputed in the gradualist camp but is seen merely as the “last strike” that led to the collapse of already weakened ecosystems and extinguished animal groups that were already in decline.

Those researchers that favor a single cause for the mass extinction at the K–T boundary emphasize the almost apocalyptic effects a bolide impact would have (Alvarez et al. 1995). This impact ejected considerable amounts of molten rock particles and dust into the atmosphere. Furthermore it produced huge tsunami-type waves that devastated the coastal plains, and an immense fireball ignited vast wildfires. The dust particles would remain in the atmosphere for months, perhaps even years, leading to global cooling and darkening. Photosynthesis came almost to a halt, at least in plants adapted to higher light intensities. The fern spike recorded from many terrestrial boundary sections testifies to this sudden decline in higher plants and the spread of the ferns, which could cope with darker conditions. As a consequence of the collapse of the ecosystems, first the consumers and then the carnivores died out within years. Those animals that did survive were preferentially small, unspecialized, opportunistic species that could feed on a variety of diets. That ecosystems were also severely and almost instantaneously hit in the marine realm is indicated by the patterns of the stable carbon isotopes across the boundary. These indicate an almost lifeless ocean after the K–T boundary (“Strangelove Ocean”; Hsu and McKenzie 1985; Zachos et al. 1989).

The normal succession in Caribbean coastal sections agrees well with this scenario (after Alvarez et al. 1995): above the Maastrichtian limestone, larger airborne particles (microtectites, glass spherules) were deposited first, then come tsunami deposits containing reworked Maastrichtian limestone and charcoal (from wildfires), then dust-borne iridium and shocked quartz, and finally we see a return to normal sedimentation. Yet in some sections, the succession of the different layers is incomplete, and sometimes there are multiple ejecta and iridium layers (some of them perhaps reworked). According to a new scenario, three impacts within 0.3–0.4 Ma around the K–T boundary best explain the patterns and all contributed to the mass extinction (Keller et al. 2003). The one producing the Chicxulub crater predated the K–T by 0.27 Myr.

16.5.10 Eocene–Oligocene transition

In a diagram of Phanerozoic extinction intensities, the Eocene–Oligocene transition period barely stands out as an important event, and yet this time marked the
most significant episode since the extinction of the dinosaurs (Prothero 1994). The Eocene was a time of warm temperatures, with widespread tropical forests, archaic mammals, and reptiles occurring above the arctic cycle (Prothero 1994; Ivany et al. 2003). Within a time period of 10 Myr, this “greenhouse” world shifted to “icehouse,” with decreased global average temperatures and markedly increasing seasonality, accompanied by major shifts in the biota of terrestrial environments and the seas (Berggren and Prothero 1992).

The record in the marine environment is one of a rather gradual turnover. A displacement of warm-adapted taxa by invading high-latitude forms is observable in both planktonic and benthic taxa and was obviously accelerated around the Middle-Late-Eocene (Bartonian–Priabonian) boundary and within the Early Oligocene (Rupelian) (Berggren and Prothero 1992). As much as 90% of the genera disappeared in some groups (Hallam and Wignall 1997). Fishes survived this period almost unaffected while among the whales, the more basal archaic whales were replaced by the first modern toothed and baleen whales (Prothero 1994).

On land, the flora changed between the Middle Eocene and Early Oligocene from widespread forests to open shrublands (perhaps with the first grasses), and the leaf record as well as the amphibian and reptile fauna show a marked cooling and drying trend (Berggren and Prothero 1992; Prothero 1994). Among the mammals, a fundamental difference between the Eocene and Oligocene faunas, the “Grand Coupure,” has long been recognized (Stehlin 1909; Legendre and Hartenberger 1992). In Europe, there is a gradual replacement of archaic by modern mammals throughout the Late Eocene and Early Oligocene with a pronounced peak of extinctions at the Grande Coupure (Hooker et al. 2004). This latter event is now dated as Early (but not earliest) Oligocene (Prothero 1994). Almost all new taxa are immigrants from Asia, which could reach Europe after the closure of the Turgai strait in the Ural region. Similar trends are observable on the other continents (Prothero 1994).

High-resolution oxygen isotope studies over the past decades have considerably helped to clarify the climatic evolution from the Early Eocene to the Early Oligocene. Global temperatures reached a peak between 52 and 50 Ma, during the so-called Early Eocene Climatic Optimum (EECO). This was followed by a 17-Ma–long trend toward cooler conditions, with a dramatic increase in δ18O at the Eocene–Oligocene boundary (Zachos et al. 2001). This latter shift in the oxygen isotope values reflects not only cooling but also a significant increase of the Antarctic ice cap. The first ephemeral ice sheets appeared already during the Late Eocene and were probably the result of both declining atmospheric CO2 levels (DeConto and Pollard 2003) and an increasing thermal insulation of Antarctica. Plate tectonic movements had led to the separation of Australia
and Antarctica and to the opening of the Drake Passage between Patagonia and Antarctica. By the end of the Eocene, the passage south of Tasmania was deep enough that the circum-Antarctic cold deep current could become established, and the Antarctic ice cap rapidly grew (Prothero 1994; Ivany et al. 2003; Kennett and Exon 2004). Yet on land, the extinctions associated with the Eocene–Oligocene transition were not simply the result of global cooling, increased seasonality, and increasing aridity but also a consequence of large-scale migrations. As an alternative or perhaps additional cause of the terminal Eocene turnover, impacts by comet showers were proposed (Poag et al. 2003). For the Siberian Popigai (100 km) and the Chesapeake Bay crater (85 km) as well as for the ejecta layer at the Massignano type section in Italy, a corresponding age has been established. Yet the biotic turnover patterns do not seem to correspond to an impact scenario (Ivany et al. 2003).

16.5.11 Pleistocene and modern extinctions

During the Pleistocene, between 1.8 Ma and 0.01 Ma, the earth witnessed large climatic fluctuations. Both plants and animals on all continents showed large shifts in their geographical distribution during this period but the extinction levels were not above background values (Alroy 1999). This is true for such disparate taxonomic groups as insects, amphibians, reptiles, birds, and mammals. Yet there is one major exception to this rule: the so-called mammalian megafauna (animals > 44 kg). Fifty thousand years ago, more than 150 genera of this megafauna were populating the continents, but 10,000 years ago, at least 97 of these genera were extinct (Barnosky et al. 2004). There have been continued debates over whether these extinctions were caused mainly by environmental changes associated with climatic fluctuations, or were the consequences of human impacts. It is undisputed that humans were responsible for the extinction of large mammals and large birds on islands such as Madagascar, Antillean, Mediterranean, East Asian Islands, and New Zealand (Barnosky et al. 2004; Burney and Flannery 2005). Here hunting and habitat fragmentation led to extinctions even in the absence of climatic change.

An important aspect is that mammalian megafaunal species on all continents became extinct but both magnitude and timing of the extinctions differed between continents (Roy 2001; Barnosky et al. 2004). The extinctions were most severe in Australia where 14 out of 16 (88%) giant marsupials succumbed. In addition, all seven genera of megafaunal reptiles and birds went completely
extinct (Barnosky et al. 2004). Humans arrived on that continent somewhere between 71,500 and 44,200 years ago, and most megafaunal species became extinct before 40,000 years ago (Barnosky et al. 2004). In North America, 33 genera (72%) went extinct (Roy 2001) within a short time interval between 11,500 and 10,500 years ago, closely correlating with the arrival of Clovis-style hunters (Alroy 1999; Roy 2001; Barnosky et al. 2004). In South America, 50 genera (83%) vanished during the arrival and spread of humans about 12,900 to 10,000 years ago. In Eurasia (excluding southern Asia), 9 genera out of 25 (36%) became extinct during two pulses (45,000–20,000 years ago, 12,000–9000 years ago). These extinction pulses correlate also with the spread and then the population increase in modern humans (Barnosky et al. 2004). In Africa, the losses were relatively mild with only 8 genera (18%). When considering only mammals > 1000 kg, the differences between continents are even more marked. In North America, all four genera were lost, Eurasia saw the demise of four out of five, but in Africa, no such genus went extinct (Roy 2001).

Many phases of human colonization were coeval with marked climate changes. Because earlier, similar climate changes were not accompanied by marked extinctions, hunting by humans (overkill) was proposed as the main mechanism responsible for the extinctions (Martin 1984), either by heavy and selective hunting (“Blitzkrieg”) or through habitat fragmentation, nonselective hunting and the introduction of exotic species (“Sitzkrieg”). The current consensus picture for megafaunal extinctions on the continents is that extinctions were most pronounced where a rapid spread and increase in H. sapiens populations coincided with marked climatic shifts (Burney and Flannery 2005). But it was not primarily large sized but rather slow breeding species (this is, in part, correlated with large body size), which were at the highest risk of extinction (Johnson 2002). Even if the proportion of deaths caused by humans was low at any one time, slow breeding megafaunal mammals were driven to extinction.

Yet the story is not over. Since the age of colonialization, the exploitation of nature has reached a new level, and the fate of the dodo (Raphus cucullatus) is just one very sad and telling example of human impact. This flightless bird was discovered in 1598 on Mauritius after Portuguese sailors first reached this island in 1507, and became extinct by 1690, not only by hunting but also by the introduction of domestic species, such as goats, pigs, and rats, which devoured the eggs and the young. The list goes on, and even extremely common species like the passenger pigeon in North America (Ectopistes migratorius) have proven to be no match for intensive hunting humans. Starting during the epoch of industrialization, exploiting nature and destroying natural habitats has proceeded...
at an ever increasing rate (Wilson 1994). There is no question that current extinction rates for plants and animals have reached a level perhaps 2–3 magnitudes above background rates (Nott et al. 1995; Pimm et al. 1995; Ricketts et al. 2005). Scaling the available estimates of current extinctions up to a magnitude where we can compare them to past Phanerozoic mass extinctions reveals that if species losses continue at the present rate, 96% of the species will be extinct within just a few hundred years (May et al. 1995; Sepkoski 1997; “Sixth” extinction). This is the maximum estimate for species losses during the most severe of all the Phanerozoic mass extinctions, the one that occurred at the Permian–Triassic boundary! Yet although the end-Permian mass extinction is no longer seen as a crisis spanning millions of years, current estimates are still on the order of a hundred thousand years. There is even further concern. As several episodes of mass extinctions have shown, even a moderate increase in global temperatures of a few degrees, if it happened fast enough, has proven fatal for life on the entire planet.

16.6 Conclusions

After more than 30 years of intensive research, the picture of life’s diversification on earth has attained an unprecedented level of accuracy. Much progress has been made in Precambrian research in the study of the oldest fossils and their environment. Major input into studies of radiations and extinctions came from geochronology, which provided a new, accurate time scale. Another important development was the establishment of a new animal systematic, and considerable advances were made in the dating of lineage splitting.

The quintessence of diversity studies, the global diversity trajectories for the Phanerozoic, have been refined in many ways, but the classical, iconographic figure of Sepkoski for the marine animals has changed little over the years. Yet many of the “dogmatic” concepts are reevaluated, a new data base is being developed, and methodologic problems receive considerable attention. What is needed for further refinements are especially studies at the local level that take into account ecological data and ultimately can be assembled into a new global picture.

Mass extinctions have received a tremendous amount of attention since 1980, and for most of them a consensus picture exists today. Emerging is that each extinction event had its own signature, and a common cause has not been found. Hot topics at the moment are the diversification of the metazoans, the Cambrian and Ordovician radiations, and here we will most likely see much progress in the next few years.

Abstract

Starting from Ernst Haeckel’s famous definition of ecology, our review considers the premises and the meaning of paleoecological research. Unlike current ecology, paleoecology has to pay more attention when dealing with “facts”: the concept of uniformitarianism is presented and demonstrates the importance of philosophical constructs for scientific work. The middle-range theory attempts to filter out false conclusions. Abiotic factors have had a strong influence on adaptive evolution; volcanism, tectonism, and climate are exemplified. Subsequently we discuss the biotic viewpoint with regard to aspects of fossil findings and in this context taphonomy, stratigraphic research, and interactions between floral and faunal environment. In a synthesis, we present three cross sections in human evolution in different time horizons (early–middle–late) to exemplify the multidisciplinarity of paleoecology and present some key events that probably altered the direction of radiations among hominids. Obviously, human evolution is not a special kind of evolution; it follows strictly the rules of evolutionary biology and hence depends undoubtedly on environmental influences.

17.1 Introducing (paleo)ecology

In a strict sense, paleoecologists try to detect all processes which have affected a fossil organism antemortem (Behrensmeyer 1992). Postmortem events are analyzed by the methods of taphonomy, and by studying diagenesis (Andrews 1992; Lyman 1996), we have to realize that these two fields are inseparably linked in dealing with fossils and the reconstruction of their environments. Here, we illustrate briefly what (paleo-) ecology is and then we discuss actualism (or uniformitarianism) as an essential aspect of paleoecology.
17.1.1 Current ecology versus paleoecology

Haeckel (1866), who introduced the term “Ecology” (German: Oecologie, nowadays Ökologie) stated:

- Ecology is a part of science that deals with the relationships between organisms and their surrounding environment, wherein we can place all conditions of being” in the broadest sense. These are of partly organic, partly inorganic nature; and both are of utmost importance for the form of organisms, because they force it to adapt to them (translated and shortened by the authors).¹

Haeckel included the following aspects in his “conditions of being”:

1. **Abiotic factors** (physical, chemical, climatic, electricity-conditions, inorganic food, composition of water and soil).
2. **Biotic factors** (all relationships between organisms).

More recently, modern ecology has been defined as “the study of the relations between organisms and the totality of the physical and biological factors affecting them or influenced by them” (Pianka 1983 p 3). Among its most interesting branches are the distribution and frequency of organisms/populations/communities, hence natality, mortality, and migration (Begon et al. 1998). It makes sense to divide ecological research into three subsections (Table 17.1).

All of these definitions are crucial when talking about ecology; however for several reasons, it is not that easy to simply insert the prefix “paleo” for the study of ancient ecologies (Andrews 1992).

There are not only strong connections between paleoecology and recent ecology but also some basic differences (Table 17.2).

---

Paleoecological research is aimed mainly at analyzing long-term trends because when dealing with fossils short-term processes (e.g., successions, micro-evolution) are not recognizable, or recognizable only with difficulty. Frequently, paleoecological analyses focus on the development of communities in certain paleoenvironments over time spans of millions of years (Stanley 1994). Despite the fact that there is a conspicuous nexus between organismic paleoecology and geological orientated facies observations, it is preferable in practice to separate the two, since both disciplines are in themselves multilayered and sophisticated networks (Etter 1994). Contemporary paleoecological questions include:

Are similar as well as different morphological characters linked to adaptations in the same kind of habitat?
Are there interdependencies between paleomilieu and life cycles/life-history parameters/population densities?
How is distribution and diversity of life on earth dependent on ecological requirements?
Can extinction events be traced back to major changes in the environmental conditions, and if so, to which?

All of these questions require a high degree of multidisciplinarity and cannot be solved only in terms of one-factor analyses. They also have to encompass multiple factors that build ecosystems like the one covering our planet.

After a short look at the approach of actualism/uniformitarianism, we will take the previous quotation by Haeckel as a guidepost for the following sections. After touching on abiotic factors we proceed to the biotic ones, and finally merge them in a third step that we designate as synthesis. In this we try to focus on hominid or near-hominid evolutionary perspectives and leave out important paleoecological aspects that refer to marine ecosystems.

17.1.1.1 “The present is a key to the past”: A valid premise?

One of the most important concepts in the geosciences is uniformitarianism, a principle introduced by the Scottish physician and geologist James Hutton (1726–1797). Originally, this was framed as an antagonist to the idea that catastrophic phenomena might have formed Earth’s surface. It was the establishment of the idea that the laws of nature stay constant that made geology a mature part of the scientific endeavor. This philosophical approach is axiomatic in physics, but it was Sir Charles Lyell, “Darwin’s guru and intellectual father figure” (Gould 1994 p 6764), who placed this idea before a broader scientific community. The application of this principle inspired Darwin, although Gould (1994) warned against the pure extrapolationism of Darwin’s uniformitarian perspective. Gould’s (1994 p 6768) attractive musings on paleontology’s meaning are more important than ever. The simple-mindedness of universal reduction to lower levels must be abandoned: “Our evolutionary world is a hierarchy of levels, each of legitimacy and irreducible worth.” Riedl (1981) also emphasized the limitations of each methodological level.

Based on Gould (1984), Etter (1994) reduced the philosophy of actualism to four principles:

1. Laws of nature do not change on Earth in time and space.
2. Processes that influenced geological phenomena in the past occur in the same manner now.
3. The speed of geological and biological processes does not change.
4. In the past the same materials and the same conditions existed.

The first two of these are methodological assumptions that are necessary to conduct inductivist research. Points three and four are less definite. As Etter (1994) points out, the adoption of all four premises may be limited due to (1) constraints of observing the past and (2) the strong fluctuations of geological phenomena which occurred long ago (e.g., the circumstances of the dinosaurs’ extinction).

Dodd and Stanton’s (1990) taxonomic uniformitarianism is a derivative of substantive uniformitarianism and an attempt to reconstruct ecological niches by assuming that the environment of a fossil will have been identical with that of the nearest extant relative. But it is obvious that reliable conclusions can only be made in this way if a fossil is a member of an extant species. This can virtually never be the case except for Pleistocene and Holocene deposits (Etter 1994), and even then there are also theoretical problems, one of which is the fragmentary knowledge we have of former ecological niches. An absence of enemies could, for example, have caused an expansion of the niche. Thus Etter (1994) admits that taxonomic uniformitarianism should be limited to fossils with extant representatives or relatives. Yet the method can be improved by investigating groups of species within a taxonomic group rather than just one.

Tattersall (1998) reviewed such provocative ideas of evolutionary biologists as Dawkins’ “Selfish Gene” or Eldridge and Gould’s “Punctuated Equilibrium” and also relativized the meaning of adaptationism (p 95: “…organisms may not be as exquisitely fine-tuned to their environments …”) in our evolutionary thinking. Therefore, we should not forget that there exists a possibility of overstraining positivism. Actio-reactio thinking is of course essential, and the only way of doing science in general; but the danger of story-telling in paleoecology is acute. We are at risk of delivering explanations for adaptations which could be true but actually might not be (see later). It is questionable if the equation: \( \text{Bauplan:environment} = 1:1 \) is satisfied.

Foley (1978) linked the past and the present by summarizing Binford’s (1977, 1981) middle-range theory: this is actually an assemblage of theories linking observable aspects of the past to processes operating today, permitting inferences about the conditions of geological and biological systems in the past. Such observations must be linked to observable past phenomena (i.e., an anatomical element) (Figure 17.1). A connecting piece between a theory (deductions and predictions from a basis of axioms) and the data is the model (which describes and predicts the variation and structure of phenomena derived from theoretical principles).
Foley (1987) also points out that there are different levels of model building, depending on behavioral (predispositional) and geological (postdepositional) factors. Furthermore, identical records might be produced by different behaviors (Hill 1984; Foley 1987), so the overlap of different models has to be taken into consideration. Four pathways are very useful for testing a theory in order to reduce the pure reflection of contemporary ideas: (1) a careful analysis of each link in an inferential chain, (2) like Binford (1981) not following the broad trend but rather looking for small details that might appear comparatively insignificant, (3) the isolation of processes that may result in similar results and assigning (theoretically/experimentally) the probabilities of various outcomes, and finally, (4) the comparative biological approach, which investigates patterns of interspecific and intraspecific variation that can be used to correlate biological variables (Figure 17.2).

17.1.1.2 Ecology and cladistics

The a priori assumption that a particular character (or character state) is the result of a particular evolutionary process may lead to far greater problems of circularity than does the incorporation of these characters into a global estimate of evolutionary history (Luckow and Bruneau 1997 p 150). These authors infer that the exclusion of ecological information from a phylogenetic analysis when testing ecological hypotheses is not only unnecessary but also “undesirable.” Luckow and Bruneau (1997) justified their arguments by concluding that character exclusion...
would partition the data in an arbitrary way and that discrete homology statements would get lost.

17.2 Abiotic factors

Throughout natural history, abiotic factors have had a strong influence on evolution, adaptive or otherwise. Environmental change has shaped habitats and the evolutionary “fates” of living systems. One fundamental aim of evolutionary biology is to understand and reconstruct the interaction of environmental abilities and the survival of organisms. Wegener (2005) wrote: “Only by summing up all fields of the geosciences may we hope to find out the “truth,” this means determining a picture that integrates all known facts in the best order and which seems to represent the utmost probability; even then we have to be aware that each discovery, regardless of which scientific field it emanates from, may modify the result”² (Translated by the authors). Early acceptance of this ignored genius’

² “Nur durch Zusammenfassung aller Geo-Wissenschaften dürfen wir hoffen, die ‘Wahrheit’ zu ermitteln, d.h. dasjenige Bild zu finden, das die Gesamtheit der bekannten Tatsachen in der besten Ordnung darstellt und deshalb den Anspruch auf größte Wahrscheinlichkeit hat; und auch dann müssen wir ständig darauf gefasst sein, dass jede neue Entdeckung, aus welcher Wissenschaft immer sie hervorgehen möge, das Ergebnis modifizieren kann.” (Wegener 2005 p 222)
appeal for an adequate scientific network might have accelerated the unraveling of Earth’s physical secrets.

17.2.1 Geological influences

17.2.1.1 Volcanism

In the truest sense of the word, volcanoes put pressure on their environment. Usually eruptions have a localized but strong influence. However, tephra (ejecta, e.g., ash or pumice) and lava do have the potential to modify water and soil chemistries, eliminating or modifying habitats over wide areas, or supporting the conservation of important fossil footprints.

Including sea bottom and continents, about 80% of the Earth’s surface has been produced by ascending melted rock. The new material cools down and hardens. This activity is primarily constrained to plate boundaries. Volcanic material creates a useful (blurred) perspective concerning Earth’s interior. Rocks also deliver nutriments, chemical resources, and minerals (Press and Siever 1995).

Feibel (1999) investigated the eruptive activity in the Turkana area of northern Kenya and concluded that the higher assumed rate (38 events per 240,000 years) indicates one significant eruption per 6,300 years. Massive eruptions can also cause global impacts since they glut the atmosphere with aerosols. Rampino and Shelf (1992) discussed the controversial idea of the Mount Toba-explosion 70,000 years ago, which might have produced a sharp cooling and consequently a shift to glacial conditions.

17.2.1.2 Tectonic aspects

Faulting within local sedimentary basins, continental plate movement, and the highland-formation through uplift may greatly affect terrestrial habitats.

Between 16 and 12 Ma, the Eurasian and the Afro-Arabian continental plates moved and allowed an exchange of the flora and fauna: e.g., an exodus of early African apes (Potts 2003). Between 7.0 and 5.0 Ma, the Atlantic Ocean and the western end of the Mediterranean were temporarily separated as Africa drifted northward. Here, a periodic drying and flooding of the Mediterranean basin occurred and huge salinity deposits were built up. Western Eurasia dried due to an evaporation and salinization phenomenon. Between 4.5 and 3.0 Ma, the Isthmus of Panama was formed by the contact of continental plates and

Modified from WoldeGabriel et al. 2000.
the following uplift (Stanley 1995). One result was the strengthening of the conveyor belt of Atlantic Ocean currents: the North Atlantic was “watered” by the warm Gulf Stream. The initiation of ice ages in the Northern Hemisphere during the Late Pliocene can be explained by the development, over 36 Ma, of isolation of the Arctic Ocean caused by a high-salinity, warm, sinking, and returning current (Stanley 1994).

The rift valley formation in eastern Africa, the uplift of western North America and the Tibetan Plateau represent examples of drying and cooling effects. Models of general circulation show that when major air currents are divided by elevated plateaus, the air is altered due to winter cooling and summer heating causing high- and low-pressure areas to form over landmasses far from the plateaus (Ruddiman and Kutzbach 1989). One consequence is a greater seasonal variation and also the creation of seasonal monsoons. The overall effect is a cooler and drier global climate (Ruddiman et al. 1989). Even geochemical weathering on rocks can be traced back to uplifts: enhanced monsoons, steepening river gradients, and faster erosional rates increase weathering. Raymo and Ruddiman (1992) suggested that global cooling might result from the deposition of carbon from the highlands into the ocean as well as from weathering responses. A consequence would be a reduction in carbon dioxide and a removal from the atmosphere. The heat-retaining function—carbon dioxide is a greenhouse gas—would disappear. Another effect occurs on the leeward side of the uplifted region: upland depletion of air moisture and precipitation cause rainshadow drying, a phenomenon partly responsible for the aridification of the African rift valleys compared with its western counterpart.

Another possibility is that the shapes of sedimentary basins are modified by the local impact of earthquakes. Availability of water to the local biota is obviously a very important factor, so the changes of fluvial systems by intrabasin faulting mechanisms are also a matter of paleoecological discussion.

Eastern Africa is a superb example to illustrate intracontinental rifting phenomena. During the Cenozoic, a system of continental rifts developed from the Red Sea and the Gulf of Aden in a southward direction from the Afar-region of Ethiopia, which is a triple junction where three developing tectonic plates come together (Figs. 17.3 and 17.4; Table 17.3). This phenomenon is widespread. A former triple junction existed where Africa and Northern and Southern America came together. The Amazon, the Mississippi, and the Niger represent rivers that run through “failed rifts.” Afar is characterized by three spreading zones and represents a small portion of oceanic crust that has been uplifted and is now part of the continent (Stanley 1994).

17.2.2 Climatic influence

17.2.2.1 Cycling planet Earth

The Milankovitch cycles (Alverson Volume 1 Chapter 12) are a consequence of the changing gravitational pull of other planets. Variation in solar heating, which is related to astronomical cycles altering orientation and shape of Earth’s orbit around the Sun, is attributed to these periodic oscillations. The solar radiation, its distribution and strength, changes over the globe in periods of 19, 23, 41, and 100 thousand years (Hewitt 2003). How can these periods be detected? Oxygen isotopes are documented in the deep-sea record and represent measurements of the global ice volume, ocean temperature, and evaporation. Around 3.0–2.5 Ma, the amplitude and frequency of $\delta^{18}$O oscillation changed significantly. Northern Hemisphere glaciation and greater aridity in the tropics correspond to this pattern. Between 900 and 600 ka, the effects of 100,000-year-long cycles of glacial forming and interglacial warming came into play (Hewitt 2003).
The 23,000-year cycle of Earth’s rotational axis intensifies African monsoons, and the millennial-scale instability causing North Atlantic iceberg discharge involving huge masses of ice rafting, melting, and a decrease of ocean salinity was also important here. Taylor et al. (1993) and Bond et al. (1997) traced this phenomenon back to decade- to century-scale fluctuations between near-glacial conditions and interglacial warmth. Raymo et al. (1998) and McManus et al. (1999) linked these conditions to the Late Pleistocene and Early Holocene.

Well-defined cycles are not necessarily well separated in terms of amplifying and buffer mechanisms. Their interactions show complex patterns, as Clemens et al. (1996) and Paytan et al. (1996) have demonstrated. Furthermore, Potts (2003 p 365) stresses that “major environmental shifts occurred episodically throughout the Quaternary and did not necessarily coincide exactly with maximum changes in temperature, moisture, or any other single factor.” Lister and Rawson (2003) called attention to the rise and fall of sea level, one major effect of the climatic ups and downs: over the past 600,000 years fluctuations of up to 120 m are documented. Inundations as well as the exposure of continental shelves created new barriers—or pathways.

17.2.2.2 Our planet’s oceans

Earth’s climates were much wetter and warmer before Middle Eocene times, and deciduous and evergreen forests dominated the natural scenery. Antarctica was full of temperate rain forests and Arctic land masses were distributed with trees (Askin 1992; Denton 1999). A strong seasonality and a general lack of aridity reduced the occurrence of grasslands and deserts. Sea ice and glaciers were limited concerning their volume expansion (Ruddiman and Kutzbach 1991). The world’s oceans were about 10°C warmer at depth than today. Furthermore, the atmospheric temperature gradient—from the equator to the pole—was much smaller than that of today (Savin et al. 1975; Shackleton and Boersma 1981).

This changes when we look at the recent situation. Since the Middle Eocene, global climate has cooled. Shackleton (1995) discussed the essential global paleoclimatic change at 2.95–2.52 Myr, and the beginning of the oscillating ice ages. Over the past 0.95 Myr, each glacial maximum was on average 5°C cooler than today and the planet was drier, e.g., much of northern Europe was covered by tundra and Africa was drier (Denton and Hughes 1981; Denton 1999).
17.2.2.3 Another unique continent: Africa

deMenocal (2004) gave a very useful overview of the African climate: as Figure 17.5 demonstrates, the combination of the seasonal migration of the intertropical convergence zone and the African monsoon causes a highly seasonal range of North African rainfall. In the boreal summer, heat over the North African land surface, centered near 20°N, draws moist maritime air from the equatorial Atlantic into western and central subtropical Africa. Accordingly, woodland and grassland savannahs flourish (Hastenrath 1985; Harris 1980).

Based partly on topographic rainshadow effects, summer rainfall in East Africa is very variable. It is also related to the westerly airstream of the African monsoon (Nicholson 1993). East Africa's subtropical rivers, such as the Omo and the Nile, are drained by the summer monsoonal runoff via the capture of moisture by Ethiopian and Kenyan Highlands. On the other hand, relative to adjacent oceans, Asian and African landmasses become cooler and a reversion of the atmospheric circulation comes about (deMenocal 2004).

Prospero and Nees (1986) showed that the changes of subtropical African summer rainfall are closely tied to West African dust export to the Atlantic. Additionally, these modifications have been linked by Giannini et al. (2003) to anomalies of the sea-surface temperature. Figure 17.5b demonstrates that Indian monsoon surface winds are interconnected with summer dust plumes of Arabia and northeast Africa (Nair et al. 1989). These winds carry mineral dust to the Arabian Sea and the Gulf of Aden. The study of mineralogical and sedimentological data reveals that wind-borne detritus “from these sources comprises the dominant source of terrigenous sediment to the eastern equatorial Atlantic and the Arabian Sea” (deMenocal 2004 p 7).

Marine paleoclimatic records The last (ca.) 5 Myr, during the Late Neogene, showed progressive step-like increases in African aridity and periodical arid–humid climate cycles. This conclusion can be drawn from marine sediments accumulating off the western and eastern margins of the subtropical North African region. The isolation of the Atlantic basin via the Isthmus of Panama and the following gradual onset of high-latitude glacial cycles at 3.2–2.6 Ma seem to have influenced African climate variation patterns (Haug et al. 2001). The onset of glacial ice rafting and modest 41-kyr glacial cycles after 2.8 Myr caused Plio-Pleistocene cooling at high latitudes. Another step was a shift toward cooler conditions and, after ca. 1.6 Myr, higher-amplitude 41-kyr cycles after 1.2–0.8 Myr (Shackleton et al. 1984).
Figure 17.5
(a) Regional map of Northern Africa vegetation zones, locations of DSDP and ODP drill sites (filled circles), and locations of selected African mammal fossil localities (open diamonds).
(b) Boreal summer (August) surface wind stress (unit vector = 1 dyne/cm²), intertropical convergence zone (ITCZ, heavy dashed line) location, and boundaries of seasonal tropospheric dust plumes off NW Africa NE Africa/Arabia. Dust plume contours were derived from haze frequency data. (c) Boreal winter (January) surface wind stress (unit vector = 1 dyne/cm²), ITCZ location, and boundary of the seasonal tropospheric dust plume off NW Africa (reprinted from Earth Planet Science Letters, Vol. 220, de Menocal, P.B., African climate change and faunal evolution during Plio-Pleistocene, P. 3–24, with permission from Elsevier.)
Variability of subtropical African paleoclimate: deMenocal (2004) summarized the patterns of marine sediment records of Plio-Pleistocene eolian export from West and East Africa:

- The variability of orbital-scale African climate variability persisted throughout the entire interval (and in some cases extending into the Miocene and Oligocene)
- The onset and amplification of high-latitude glacial cycles was closely linked to the onset of large-amplitude African aridity cycles
- A gradually increasing after 2.8 Myr of eolian concentration and supply (flux)
- At 2.8 (±0.2), 1.7 (±0.1), and 1.0 (±0.2) Myr, step-like shifts in the amplitude and period of eolian variability
- There is evidence for $10^4$ to $10^5$ year “packets” of high- and low-amplitude paleoclimatic variability which were paced by orbital eccentricity.

deMenocal (2004 p 8) described the marine record as “a succession of wet-dry cycles with a long-term shift toward drier conditions, punctuated by step-like shifts in characteristic periodicity and amplitude.” de Menocal (1995) interpreted subtropical African climate prior to 2.8 Myr varying at the 23–19-kyr period, mainly as a result of Asian monsoonal variability. At 2.8 (±0.2) Ma, there was a shift toward climate variation periods longer than 41 kyr and after 1.7 (±0.1) Myr the cycles lengthened again, and an eolian variability-shift toward longer and larger-amplitude 100-kyr cycles after 1.0 (±0.2) Myr occurred. The onset and growth of high-latitude ice sheets and cooling of the subpolar oceans were synchronous with these shifts in the African eolian variability (Shackleton et al. 1990), and there was a coupling between high- and low-latitude climates after the glaciation-onset near 2.8 Ma (deMenocal 1995).

Dupont and Leroy (1995) showed that a pollen record from Site 658 documents the phenomenon of greater variability and progressively xericasive vegetation after ca. 3.0 Mya and concluded that a shift toward a drier and cooler African climate occurred during glacial maxima. The pollen record correlates with oxygen isotopes indicating that large global ice volume and deep-sea temperatures correspond to aridity. These authors conclude that a comparison of short-term fluctuations of periods before and after 2.5 Myr demonstrates “that obliquity forcing of northwestern African climate started with the first large glaciations in the Northern Hemisphere” (p 297).

Which phenomenon is the fundamental impulse generator for African climate variability? The Plio-Pleistocene succession of sapropel layers in the Mediterranean Sea could be interpreted as a consequence of orbital precession
(Hilgen 1991). Enhanced monsoonal and Nile river runoff led to increased Mediterranean stratification and reduced ventilation of the deep eastern basins (Rossignol-Strick 1985). During these humid periods, organic-rich layers were deposited. However, another stimulating factor could be a covariation of African climate with the high-latitude climate cycles at the 41- and 100-kyr periodicities, which is what marine sediments actually suggest.

deMenocal (1995, 2004 p 10) tried to reconcile the two different points of view “by acknowledging that precession was the fundamental driver of African monsoonal climate throughout the late Neogene, but that high-latitude glacial cooling and drying effects were superimposed on this signal only after 2.8 million years.”

17.2.3 Physical (paleo)geography or the beauty of mosaics

The African continent extends virtually equidistant into both the Southern and the Northern Hemispheres. It includes about 20% of the world’s land surface and stretches 8,000 km from north to south. The configuration of the bordering oceans and landmasses has remained almost the same from the Early Pliocene up until today (O’Brien and Peters 1999).

Based on the pioneering work of Lobeck (1946), O’Brien and Peters (1999) subdivided Africa into different physiographic regions (Figure 17.6). In Low Africa, during most of the Pliocene, all of the interior basins may still have lacked outlets to the sea, a condition not existing today. Prerift Africa’s (Miocene–Pliocene) interior basins and associated drainage systems are nowadays etched by old deltas, strandlines, old terraces, and alluvial deposits. This might indicate (at least) seasonally expansive internal lakes, e.g., the Paleolake Congo. This was probably a perennial water body up to at least the Late Pliocene, and its eastern catchment extended to the High Interior Plateau and the volcanic highlands of the Eastern Rift Belt (O’Brien and Peters 1999).

In the Oligocene, High Africa was tectonically driven by the African Swell, which was active again in the Late Pliocene and Pleistocene. Different effects have influenced southern and eastern Africa: during the Late Pliocene, local environmental and increasing subregional fragmentation took place. During the Early as opposed to the Late Pliocene—up to 3.0 Myr—the rift grabens associated with doming were shallow and also at higher elevations than now (Brown 1995). The Ethiopian Massif was probably lower than now, while the High Eastern Interior Plateau may have been higher (Feibel 1999). Between 3.0 and 2.0 Ma, an uplift of rift shoulders by 1,000–1,500 m and a concomitant major subsidence of rift
grabens occurred: (1) first in the Eastern Rift Belt areas and in the Afar-region and later (2) in the Western Rift Belt, where some of the uplifted flanks rose to 4,000 and more meters above sea level (Partridge et al. 1995a, b). The eastern drainage perimeter for the Congo Basin was established by the Escarpment Mountains of the Western Rift Belt. They also caused a diversion of the westward drainage from the Eastern Rift Belt and the Interior Plateau, into the Sudd. The Rift Valley Domain of the East African Highlands was particularly perforated by active volcanoes (O’Brien and Peters 1999).

Africa’s Southern Platform was formed by subsidence events resulting in local fragmentation of the environment (exceptions: areas immediately adjacent to subsided or uplifted margins) and by broad-scale regional uplift. The Southern Platform was apparently lower in elevation than nowadays by some 200 m in the southern escarpment mountains and by as much as 1,000 m in the extreme southeast. The Transvaal, however, was somewhat higher than today (maybe about 400 m). Furthermore, the paleolakes of the Southern Platform are of special interest for hominid ecogeography (e.g., Makarikari). The grabens of the
Western and Eastern Rift belts in the East African Highlands contained intermittent rivers and lakes. Lake Malawi, however, obtained its present shape only at the end of the Pliocene (Partridge et al. 1995b; O’Brien and Peters 1999).

### 17.3 Biotic factors

Together, abiotic factors build a framework for living spaces that frequently harbor more than one population (Ziegler 1992). These spaces are called *biotopes*, with their enclosed organismic communities characterized as *biocenoses*. These often include highly adapted and specialized species in numerous ecological niches; together they build so-called ecosystems or *biomes*. The goal of paleoecologists is to reconstruct these systems or paleoenvironments based on organic and inorganic remains.

In the following section, we concentrate mainly on fossils, their interpretation, and the surrounding factors that influence them and thus have to be analyzed when reconstructing paleoenvironments. We touch on questions of *post mortem* processes, stratigraphic research, and coevolution. Due to the fact that we spotlight hominid and accordingly terrestrial evolution, we omit an extensive debate on plant fossilization and exclude aquatic ecosystems.

#### 17.3.1 Fossils

A fossil is any remain or trace of any organism from all past periods. They are the key elements of paleontology and consequently of paleoanthropology and paleoecology and act as *containers* or *archives* that preserve information over a long period. Scientists who deal with fossils have to find the right *tools* to open and unravel the secrets lying within. We try to illustrate some of these “tools” and enlighten several approaches of paleoecological research.

**17.3.1.1 What happened *antemortem* and what *postmortem*?**

It is unlikely that an organism will be preserved through time after death. Less than 1% of all organisms are handed down to us (Ziegler 1992; deMenocal 2004), especially in terrestrial and tropical conditions, as we see in the case of hominoids (Carroll 1988; Martin 1990; Stanley 1994; Andrews 1990). Due to this, the density of relevant paleoanthropological fossils is very low—approximately one fossil per one hundred generations—and there are a lot of gaps that effect the phylogenetic and ecological reconstructions scientists strive for (see later). Besides this, most fossils are fragmentary or incomplete and require reconstruction by means of all
available methods, now including 3D-reconstruction using CT, MRT, or surface scanning (Ulhaas Volume 1 Chapter 27). Additionally, we have to consider the limited erosion of noteworthy ancient fossil sites on the African continent, since most areas are covered with tropical forest, as well as the political and financial circumstances that impede excavations on the other hand.

Every fossil contains a great deal of information on the evolutionary history (phylogeny), physical organization (morphology), and lifestyle (ecology) of the populations the organism once belonged to. Under ideal circumstances, it is possible to extract most of this information by careful analyses of the taphonomic and diagentic processes involved. Taphonomy, as a special field of paleontology, represents the description and causal analysis of all factors that influence an organism after death (necrology and biostratinomy) (Figure 17.7) and subsequently all processes of embedding and fossilization (Efremov 1940; Lyman 1996; Grupe Volume 1 Chapter 7). In contrast, diagenesis characterizes only the biological, physical, and chemical alteration of the mineralogical elements affecting fossil-bearing sediments and is part of taphonomy and the lowest grade of rock-metamorphism (Stanley 1994; Lyman 1996; Conroy 1997).

The possibility that an organism will be fossilized after death—its transition from the bio- to the lithosphere—depends on many environmental factors (Foley 1978; Henke and Rothe 1999). With few exceptions, the soft tissue undergoes the physiological processes of decomposition and decay in the first phase after death (necrology), and normally only hard materials like teeth, bones, shells, and rarely scales and horn are suitable for being mineralized and thus fossilized. The most important participants in this process are: calcium in the form of calcite and aragonite (CaCO₃), bone apatite (Ca₅(OH)(PO₄)₃), silicic acid—skeletal opal (SiO₂), chitin, cellulose, and scaffold proteins (spongine, ceratine).
17.3.1.2 Who are you? Where do you come from? What brought you there?

The only way to reconstruct ancient ecosystems is to examine the fossil record and elucidate the internal and external influences that led to the life forms we try to understand and explain. Following Etter (1994), there are three crucial requirements that have to be fulfilled when analyzing fossils:

1. Accurate determination and systematic classification of the collected specimen.
2. Putting all investigated profiles in a temporal and stratigraphical order as precisely as possible.
3. Understanding the ecological context and the specific adaptations of the organisms that enable it to live in particular environments.

In brief, we have to study fossils in context to understand the processes occurring in interrelated evolving systems (Figure 17.8).

17.3.1.3 Who?

Taxonomic classification is not only essential but also complicated and depends on whatever evolutionary theory, species concept, and taxonomic approach the
researcher prefers (Delson 1990; Foley 1978; Tattersall 1992, 1996; Wood 1992, 1996, Wood and Collard 1999; Wolpoff 1999; Sarmiento et al. 2002). All these questions go beyond the scope of this chapter and are discussed elsewhere in these volumes (Ohl Volume 1 Chapter 4). We need to overcome the subject–object problem (Stadler et al. 1977; Vogel 2000) when analyzing how we were “becoming human,” or even when assembling or disassembling new genera or species—not to mention new hypotheses or theories—as soon as possible after finding new hominid remains. In the words of Eric Delson: “The paleoanthropology community must look quite Pavlovian to outsiders—we all drool predictably every time a new fossil is discovered” (Delson 1997 p 445). Obviously, new fossil findings complicate the puzzle of primate and hominid evolution (Foley 1991; Tattersall 1992).

Since Darwin’s ideas about natural selection and his groundbreaking theory of evolution via selective forces were published in 1859, much has been learned about the processes that generate species and the debate is still in progress. Using the individual specimens that constitute the fossil record, we can indirectly scrutinize ancient organic systems at definite points in time (“Semaphoronts” sensu Hennig 1982). One affiliated evolutionary theory, “punctuationism,” (antonym: gradualism) postulates rapid evolutionary development at the nodes of the “Tree of Life,” and long periods (branches) with slow rates of evolutionary changes. Associated is a crucial problem of fossil research, for the chance of finding “node-fossils” (once called “missing links”) is significantly lower than of finding “branch-fossils.” Essentially, human evolution is strongly embedded within the framework of evolutionary biology and has to be seen as a chain of adaptive radiations (Foley 2002) and extinction events.

17.3.1.4 Where and when?

One of the most important factors here is the time dimension and thus the absolute and relative determination of age (dating). Stratigraphers subdivide sediment layers chronostratigraphically and put them in a hierarchic system (Table 17.4; Figure 17.9). Each unit within a stratigraphic system has been defined by means of a basal Global Standard Section and Point (GSSP) by the International Commission on Stratigraphy. Absolute dating, or chronometrics, is done by direct chemical (e.g., amino acid racemization) or physical (e.g., radiometric, thermoluminescence, magnetism) analyses of bone tissue, rocks, or fossil material in the facies of interest, and different techniques attain different time

---

3 Facies: the sum of all primary rock characteristics; incorporates inorganic (lithofacies) and organic (biofacies) elements.
Relative dating methods are tightly related to the theory of, or directly on, stratigraphy and the idea of marker fossils, primarily developed by Nicholas Steno, a Danish anatomist, and upgraded by William Smith (alias “strata Smith”), an eighteenth-century English engineer (Ziegler 1992; Stanley 1994; Rothe 2000). Their perceptions led to three principles of sedimentation: (1) younger deposits overlie the older ones from the bottom up, (2) in the initial state all layers are approximately horizontal, and (3) sediments extend laterally and can be parallelized over large areas (Rothe 2000).

Murphy and Salvador 1999.
A further important law was established by Johannes Walther, a German geologist and student of Ernst Haeckel, who based his inferences on the Swiss geologist Amanz Gressly’s fundamental contributions on stratigraphy in the eighteenth century and stated that the vertical succession of facies reflects lateral changes in past environments (Cross and Homewood 1997).

Stratigraphic research can be roughly divided in three parts that differ in materials and methods:

(a) *Lithostratigraphy* deals with the sequence and succession of sedimentary beds to yield diachronic zones; only a few “key beds” are nearly isochronic (Behrensmeyer 1992; Stanley 1994).

(b) *Biostratigraphy*, which is based on organismic evolution, shows overlapping zones by analyzing facies-specific marker or index fossils that can be deemed as isochronic (Stanley 1994). Age estimations become more precise, the more closely index fossils are related (Behrensmeyer 1992). The lifespan of a fossil species, referred to as its “zone,” ranges from the first appearance of that species until a subsequently following species replaces it. Biostratigraphic timescales are often bound to a specific area. Both approaches offer the possibility of correlating sediments and time horizons continuously in regional areas (Parastratigraphy) and worldwide (Orthostratigraphy).
Chronostratigraphy, rock layers (strata) are sequenced and classified by absolute dating methods.

Christian Leopold von Buch, an eighteenth-century German geologist, popularized the term “index fossils” as a marker for the correlation of contemporary strata, based on considerations by Charles Darwin and Charles Lyell concerning the irreversibility of changing morphologies through evolutionary time. Index fossils have to meet a number of requirements: (1) worldwide distribution, (2) rapid development that means a visible short time span of one species, and evident morphological differences in comparison to other species, (3) high number of individuals, (4) high chance of being preserved (Carroll 1988; Ziegler 1992). Obviously, marine organisms (plankton and nekton) are ideally suitable as index fossils, and for that reason paleontologists often focus on aquatic micro- and nanofossils to date sediments (e.g., foraminifera, diatoms). But macrofossils are also appropriate for stratigraphic positioning; these include teeth (Kullmer 1999), and the hard tissues of smaller multicellular species (e.g., ammonites, graptoliths, conodonts). In opposition to index fossils, there are so-called facies fossils that are important for the characterization of a certain milieu with particular ecological conditions; early hominids fit in here. Problems for the chronological determination of strata are produced by geomorphological events like earthquakes, volcanism, dislocations, and disconcordance on the one hand and organism-induced disturbances like bioturbation and digging on the other hand.

A special case in stratigraphy is sequence- or cyclostratigraphy, which corresponds to the global correlation of tectonically independent eustatic sea level fluctuations that happen synchronically in the form of transgressions (sea level raises over supratidal area) and regressions (sea level falls under the lowest tide gage) that are reflected in terms of changing communities (terrestrial/aquatic) and graphical curves. Further methods of dating involve measurements of cyclic events, e.g., seasonal temperature changes, among others: paleomagnetism, palynology (microflora and -fauna, e.g., spores, pollen, ostracods, radiolarians), dendrochronology (counting annual tree rings), dentin annulations (counting tooth dentin layers), diverse luminescence dating methods, stable isotope analysis in ice- or deep-sea cores and microfossils (Lee-Thorp and Sponheimer Volume Chapter 9). Investigations of paleolimnological detritus layers are a method once developed by the Swedish scientist Baron de Geer in 1878 and denominated as the exploration of “varves” (Swedish term that stands for “periodical recurrence”), annual laminated sediments in paleolakes. These methods all miss a link to “absolute” time, i.e., there is, with the exception of tree
## Table 17.5
An overview of dating methods (relative and absolute)

<td>Electron spin resonance</td>
<td>Artifacts/fossils are exposed to radiation that predictably changes the magnetic field of the object (nondestructable)</td>
</tr>
<tr>
<td>Thermoluminescence dating (TL)</td>
<td>When reheating artifacts, the emitted light of specific crystals is proportional to the amount of radiation absorbed since the material was last heated, thus, provides a method to date pottery, hearths, fire-heated rocks, and burned minerals</td>
</tr>
</tbody>
</table>
Optically stimulated luminescence (OSL)  
Similar to TL, uses light to innervate vacated electrons in sediments, comparisons could be made through sediments with a known amount of added radiation

Fission track  
Uranium (U\(^{238}\) and U\(^{235}\)) radioactive elements create fission tracks by spontaneous splitting of Uranium atoms and therefore exposing high amounts of energy that destroy the crystal lattice in a mineral

Oxidizable Carbon ratio (OCR)  
Soil bodies are analyzed to determine the linear progression of slow humus and charcoal recycling through time with an increase in readily oxidizable carbon and a decrease in the total amount of organic carbon

Potassium–Argon dating (K\(^{40}/\)Ar\(^{40}\))  
The measurement of the accumulation of Argon in a mineral over time

Argon–Argon dating (Ar\(^{39}/\)Ar\(^{40}\))  
Comparison of the amount of Ar\(^{40}\) and Ar\(^{39}\); Ar\(^{40}\) is a stable isotope, thus does not decrease in time, whereas Ar\(^{39}\) is radioactive and consequently decreases over time

Radio-Carbon dating (C\(^{14}\))  
Age estimation for organic materials by measuring the disintegration of radioactive C\(^{14}\) since an organism died, data indication is given by years before present (BP) whereas “present” means exactly AD 1950

Uranium–Thorium dating (U\(^{234}/\)Th\(^{230}\))  
Comparison which uses the properties of radioactive half-life U\(^{234}\) and Th\(^{230}\), measures the equilibrium between these elements and not the accumulation of a decay product

Uranium–Lead dating  
The ratio of radioactive Uranium and Thorium isotopes to Lead as decay product, dating of rock material with a tremendous time depth of billions of years

Thorium–Lead dating  

Rubidium–Strontium dating  
Stable isotope ratio \(^{87}Sr/^{86}Sr\) is measured in rock material

Racemization  
Amino acids as subunits of proteins are widespread in organisms; living organisms contain only L-amino acids (turn polarized light to the left), in dead organisms L-amino acids degrade stepwise to D-amino acids (turn polarized light to the right) until the amounts are equal, thus, the ratio between both conformations provides information about the age of a sample (5,000–ca. 200,000 years depth)

\(^{2}H, ^{13}C, ^{15}N, ^{18}O, ^{34}S\) stable isotopes  
These isotopes are found for several reasons in different amounts in sample materials of different kinds and could be useful for agricultural, archeological, ecological, nutritional, geochemical, or medical research

rings, no determination of a “null-varve,” a starting point (Rothe 2000). An overview of relative and absolute dating methods is given in Table 17.5.

17.3.1.5 What context?

Biotic information may be obtained from body fossils that deliver morphological insights (comparative morphology) and from trace fossils that contain ecological information in the form of organic tracks and inorganic marks (ichnology, e.g., footprints of Laetoli). In the case of body fossils, we should pay attention to the immense differences between life, death, and fossil assemblages (Figure 17.10). A biocenosis simply represents all living species, i.e., the extant “community” in an ecosystem; in contrast, paleobiological remains are differentiated in autochthonous (Thanatocenosis = death or indigenous assemblages, in situ communities) and allochthonous (Taphocoenosis = fossil assemblages) extinct communities, whereas the latter could be affected by little transport events.
(parautochthonous) or represent a mixture of local species and species that are brought in. Differences between life and fossil assemblages may result from “displacement” of various kinds (transport, accumulation, disarticulation, etc.), scavenging, destruction of hard materials (bio-erosion, abrasion), obliteration of specific elements (calcite vs. aragonite), etc., all of which may lead to misinterpretation in terms of taxonomy, ecological, and chronological placement of fossils.

However, even in contemporary communities, it is complicated to sort out decisive external and internal factors and to show which weighting each have on specific developments in an ecological system.

17.3.2 Flora, fauna, and a touch on coevolution

There is—and always has been—a constrained relationship between flora and fauna. Since the first algae produced large amounts of oxygen, completely changing the atmosphere, animals and species have had different effects, although one can assume a comprehensive pattern of coevolution. To put it simply, coevolution or mutual selection is the process of reciprocal influence exerted by entities (mostly species) in an ecosystem (Begon et al. 1998), e.g., predator–prey or parasite–host relationships. The association of insects that need nectar and plants requiring pollen transportation presents a common example. In the case of primate evolution, Sussman (1991) hypothesized that primates evolved in conjunction with the radiation of angiosperm plants and developed terminal branch feeding on nectar and flowers (Bloch and Boyer 2002; Silcox et al. Volume 2 Chapter 1). “Sussman has proposed that grasping extremities and nails on the digits evolved for eating fruit on terminal branches of angiosperms” (Sargis 2002 p 1564). Presumably, our own ancestors began to walk upright long before they developed larger brains, since monotonous coverage of the landscape by tropical forest was beginning to fail due to climatic changes from warm and wet to arid and cool conditions in the Late Miocene (Vrba 1985; Bobe et al. 2002; Bobe and Behrensmeyer 2004). Sussman et al. (1985) and Rayner et al. (1993) suggested that, throughout the Pliocene, australopithecines showed arboreal and bipedal tendencies in a mosaic-like habitat that was marked by significant patches of subtropical forest, large areas of grassland, and savannah of all kinds. “Upright posture, large brain, tool making, and other hominin characters as adaptations to a savannah habitat must be rethought, at least in the case of A. africanus” (Rayner et al. 1993 p 228; for further discussions on the origins of bipedality see Harcourt-Smith Volume 3 Chapter 5 and Senut Volume 3 Chapter 6). Other factors, e.g., isolation, niche boundary shifts, and small population size could also be a kick-off for
evolutionary “innovations” as we find them in hominids (Wolpoff 1999; Henke and Rothe 2003). Just a few steps further in our evolutionary history, and in the debate concerning early Homo as well, we are faced with a huge amount of different hypotheses that aim to link environmental constraints to specific adaptations and morphological transformations (Vrba Volume 3 Chapter 4).

Because of the insufficient preservation of plants in toto, caused by increased decomposition in aerobic and particularly tropical conditions, paleobotanists rely heavily on pollen, spore, and phytolith analyses (Jolly et al. 1998; Elenga et al. 2000; African Pollen Database). However, such things can be dispersed well away from their original habitat through wind and water (Andrews 1992). Density and distribution of these palynological units in sediment layers give us an idea about the allocation of specific plant families, spatial scales of retraction or expansion, and potential plant food proposed. For example, isotopic data on hominin diets have shown an involvement with C₄ grass-foods (Lee-Thorp and Sponheimer Volume 1 Chapter 9; Sponheimer and Lee-Thorp Volume 1 Chapter 18). Large herbivores (e.g., gramineous, foliaceous) are bound to the availability, dispersal, and capacity of particular plants; subsequently, hypotheses about migrations of herds and “predator-prey” relationships between the latter, carnivores, and early hominines, may respectively achieve wider temporal and spatial scales. Bovids are the most common faunal element at most Neogene hominid fossil localities and are often used as indicators to understand Plio-Pleistocene hominid ecological and behavioral changes (Vrba 1995; Kappelmann et al. 1997). Besides, the strong interrelations between fossil species, phytogeography, climate, biogeography, and faunal conditions could lead to improved recognitions of “turnover pulses” in ecological networks and reflect the importance of environmental changes on faunal adaptation, selection, and evolution (Foley 1978, 1994, 1995, 1999; Potts 1998a, 1998b; Lahr and Foley 1998; O’Brien and Peters 1999; Owen-Smith 1999; Vrba 1995, 1999, Volume 3 Chapter 4; deMenocal 2004; Hernández Fernández and Vrba 2006).

17.4 Synthesis

Modifying Dobzhansky’s credo (1973) we state that: Nothing in Evolution makes sense except in the light of ecology. Corresponding to this “Ecolution,” we try to depict cross-sections in three time horizons (early–middle–late) of hominid evolution from ca. 7 Ma until today (Figure 17.11). This should provide a basis for showing how many different viewpoints have to be captured when looking at a complex process like hominoid and hominid evolution. It does not
Summary diagram of paleoenvironmental data and hominid evolution, compiled from different authors. There is a clear linkage between hominid evolution, macro- and micromammal report, climatic changes, stable isotope data, and the dispersals within and out of Africa. Seemingly, colder and more arid conditions combined with adaptational changes in hominids initiated several processes that led to the currently accepted patterns of biogeographical processes in hominid evolution. H. erectus was the first hominin species that spreads into the Old World. The taxonomic relationship between late hominin species is by no means completed. The evolution of stone tools comprises the last 2 Myr and leads to an explosion of artistic expression ca. 18 ka.
Paleoecology: an adequate window on the past?
claim to circumscribe all factors in all periods; it can only provide insights and surely leaves many perspectives unseen.

But is there an “ideal” environment that can be hypothesized for the evolution of African hominids? This and other questions are discussed in this section. Two different kinds of hypotheses can be discerned: (1) the habitat-specific and (2) the variability selection hypothesis. The former considers faunal adaptations to a specific environment, while the latter emphasizes the importance of climatic instability as a trigger for adaptive changes.

Modern interpretations support a step-by-step development of drier, cooler, and more open conditions since the Late Miocene. The influence of an arid-adapted fauna on early hominid evolution at the Mid-Pliocene (near 3.2–2.6 Ma) and the aridification shift (Bonnefille 1983; deMenocal 1995; Dupont and Leroy 1995) are viewed especially as catalyst functions for human evolution.

Vrba et al. (1980, 1998, 1995 Volume 3 Chapter 4) is a prominent advocate of the turnover pulse hypothesis that derives from the habitat-specific hypothesis, itself a variation of the savannah hypothesis. Fundamental shifts in African climate—2.8, 1.8, and 1.0 Ma—initiated the so-called “turnovers.” These turnovers are focused bursts of biotic change. For example, between 3.0 and 2.5 Myr many first appearances were of grazing species. This pattern links aridity and expanding grasslands to faunal changes (Vrba 1980; Bobe and Eck 2001). Graphically, the pulses are defined via clustering. Authors, such as Behrensmeyer et al. (1997) or Werdelin and Lewis (2001), do not, however, support this important view of climate- and hominid-evolution interaction.

To make things more complicated, the area for the evolution of bipedality might have been forest habitats, not savannah (Rayner et al. 1993). Concerning the evolution of early tool-making hominids, mosaic zones of grass- and woodland may have stimulated our evolution (Blumenschine 1986).

On the other hand, the variability selection hypothesis advocates the importance of climatic instability for introducing (1) genetic plurality, (2) natural selection, and (3) faunal innovations. Potts (1998b) suggested that many of the largest African faunal evolution events occurred when there were increases in the amplitudes of paleoclimate variability (such as modifications in the durations and amplitudes of orbital-scale wet-dry amplitudes). Potts’ (1998 p 82) view stresses the inconsistency of selection over long time spans and “thus departs from the prevailing paradigm of adaptive evolution via long-term directional selection.” As many biologists take a close match that evolves between an organism and its specific environment (and which can be definitively confirmed as most organisms are indeed habitat specialists), the variability-selection model proposes that lineages experience factors over time that disrupt close connections.
to any specific environment—a decoupling mechanism separating the organism from any environmental state.

17.4.1 Early phase: Forerunners among Miocene primates

In the Late Miocene (23.8–5.3 Ma), the hominoids, including Hylobatidae and Hominidae [Ponginae/Orangutans and Homininae/African Great Apes and Homo; sensu Groves (2001)], had reached their greatest abundance and diversity, and with little doubt human origins lie somewhere within this group (Conroy 1997). Niches now occupied by cercopithecoids were only now additionally exploited by hominoids in Africa (Fleagle 1999). The fossil record of Early, Middle, and Late Miocene is fairly good and includes Proconsulidae and Oreopithecidae as well (Rasmussen Volume 2 Chapter 3; Begun Volume 2 Chapter 4). However, the search for the root of hominid evolution and additionally for “… the identification of hominoids among the various genera and species of fossil apes from that epoch has proved a fruitless exercise thus far” (Fleagle 1999 p 483). Some propose Dryopithecus as a possible predecessor of the clade that includes Great Apes and Humans; others suppose Ouranopithecus to be directly ancestral to later humans. The earliest fossils that are proposed as probable hominid ancestors are Ardipithecus ramidus (ramidus/kadabba) 5.2–4.4 Ma from Ethiopia (White et al. 1994; Haile-Selassie 2001), Orrorin tugenensis ~6 Ma from Kenya (Senut et al. 2001), and Sahelanthropus tchadensis 6–7 Ma from Chad (Brunet et al. 2002). All these specimens were found in the last 10 years probably because excavation campaigns were targeted toward the “roots” of hominids and the divergence point between apes and hominids, respectively. There is much debate about the “ape-or-human” status, the morphological features, and the changes that have to be carried out on the tree of human evolution (Gibbons 2002), and of special interest here are the ecological circumstances around 7–4 Ma that these species confronted.

Ardipithecus is the name given to 5.8–4.4-Myr-old fossils from the Middle Awash area of Ethiopia. Haile-Selassie (2001 p 178) declared Ardipithecus to be the genus that “… postdated the divergence of lineages leading to modern chimpanzees and humans.” The fossils are associated with a relatively wet and wooded paleoenvironment (Haile-Selassie 2001; WoldeGabriel et al. 2001). WoldeGabriel et al. (2001 p 175) suggested that similar habitats were found in the case of Orrorin (see later) and therefore that “… these findings require fundamental reassessment of models that invoke a significant role for global climatic
change and/or savannah habitat in the origin of hominids.” Associated vertebrate fossil assemblages indicate woodland/forest habitats and small areas of open grassland around lake margins. Among the micromammals the rarity of lagomorphs shows that open grasslands are not well sampled in the habitat of *Ardipithecus*. Moreover, closed wooded environments, where fossils are less likely to be preserved, may explain the low numbers of hominoid/hominid fossils in the Late Miocene. Haile-Selassie (2001) assumed that a foot phalanx (AME-VP-1/71) gives a hint of an early form of terrestrial bipedality corresponding to locomotory abilities in *Australopithecus afarensis* and that dental characters like lower canines are exclusively shared with early hominids.

East African *Orrorin* seems to fall somewhere between the African Great Apes and humans and thus “... accords with the East Side Story proposed by Coppens” (Senut et al. 2001 p 142). The “East Side story” is a construct that invokes the geomorphologically induced allopatric development of African Great Apes and hominids (~8 Ma) in the placement of the cradle of mankind in eastern Africa between the Great Rift Valley and Indian Ocean (Coppens 1987, 1999; deMenocal 2004). A general trend of worldwide cooling, the extensive increase of grassland, and the retraction of tropical forests, rainforests, and wooded savannas are perceptible ~8 Ma. At the same time, a rifting process and an uplifting of the western rift shoulder led to the appearance of a topographic borderline that placed them in the more and more arid eastern part in the rainshadow of the wetter western part (Pickford 1990). This eastern “isolation” for several million years might have been behind endemic peripatric genetic drifts and consequently the origin of hominid features (Coppens 1999). After analyzing and interpreting postcraniual morphological features, Pickford et al. (2002) assumed *Orrorin* to have been a habitual biped with the ability to climb trees, and they found several apomorphic characters shared with australopithecines and *Homo* but none with *Pan* or *Gorilla* (Senut Volume 3 Chapter 6). The habitat of *Orrorin* was reconstructed, from faunal remains and geological analyses of the Late Miocene Lukeino Formation in the Tugen Hills of Kenya, as a mosaic of open woodland and forests around a lake. *Orrorin* seems to be a representative of a typical “edge species” that lived on the frontier between environmental units (Sussman and Hart Volume 1 Chapter 23). Associated faunal remains stem from colobines, carnivores, and ungulates (Pickford and Senut 2001).

*S. tchadensis* was found in Central Africa, in the western Djurab desert of Chad (Brunet et al. 2002). The locality is interesting because it lies far west to the Rift. Following the discovery of *A. bahrelghazali* in 1995, there was no further evidence for a western dispersal of hominids (Brunet et al. 1995) until *Sahelanthropus*, whose ecological circumstances are remarkable insofar as they are similar...
to those of the eastern fossil sites. This raises the possibility to analogize evolutionary constraints for hominids in the eastern and western different areas. Vignaud et al. (2002) suggested that *Sahelanthropus* lived close to a vast lake with swamp areas and rivers (inferred from fish and amphibious forms) and not far from a sandy desert. As deduced from basicranial and facial structures, Brunet et al. (2002 p 150) concluded that there are clear similarities between *Sahelanthropus* and “... later fossil homininds that were clearly bipedal.” The faunal record shows animals associated with gallery forest, open grassland, and savannah (primates, rodents, equids, bovids, and carnivores). All these observations led Brunet and colleagues to arrive at the conclusion that *Sahelanthropus* lived in a more mosaic-like habitat than *Ardipithecus*, *Orrorin*, and the australopiths.

Still, all three new genera are represented by little fossil evidence and lack intraspecific comparisons, limiting inferences facilitating placement of these fossils into the ape or the human lineages (Brunet et al. 2002; Wolpoff et al. 2002; Wood 2002; Senut Volume 3 Chapter 6). Although there is a consensus from fossil and molecular evidence that the human lineage diverged from that of the chimpanzees between ~6–8 Ma, many questions linger pertaining both to their taxonomic classification (Begun 2004) and the reconstruction of the paleoenvironments these “ape-men” lived in. “The solution is in the mantra of all paleontologists: We need more fossils!” (Begun 2004 p 1480).

### 17.4.2 Middle phase: “Chewer” and “Thinker”

Around 2.4–2.0 Ma, the genus *Homo* first appears in the fossil record of Africa. Its definition and the establishment of a hypodigm have given rise to a labyrinth of ideas and approaches about the number of species involved (Foley 1991; Tattersall 1992; Collard and Wood Volume 3 Chapter 8), the morphological variability, distinctions from the australopiths, and phylogenetic relationships. The crucial questions regarding the borderline between *Australopithecus* and *Homo*, and exactly which forms gave rise to genus *Homo* and originated the “robust” lineage around 2.5 Ma, are still unanswered. From the ecological point of view the crucial question is: “Why did these two lineages split off?” Vrba (1988) provides an overview of general hypotheses that relate environmental changes to biotic evolution and thus provides a basis to speculate about divergence processes (Table 17.6).

Late Pliocene and Early Pleistocene strata contain a number of hominid fossils that obviously belonged to different morphotypes and ways of living. On the one hand, there are robust forms with large faces, huge supraorbital structures, a small brain, and enormous masticatory capacities; on the other hand are forms with small
faces, larger brains, reduced supraorbital features, and reduced size of upper and lower jaw. The latter are associated with the first 2.4-Ma-old lithic tools (“pebble-tools” and “choppers”) as attributed to the Oldowan industry and “handy man” H. habilis. It remains doubtful that australopithecines maintained the kind of Osteodontokeratic culture (bone, teeth, and horn) that Raymond Dart (1957) proposed.

We focus here on the outstanding trends that divide two temporally sympatric genera and morphological/evolutionary “lineages”: Paranthropus and early Homo. The different ecological niches that could have been occupied by the species of both genera are limited by their basic needs as (1) large mammals, (2) terrestrial primates, (3) dwellers of tropical gallery forests/open savannah- or grassland-habitats, (4) interspecific competitors, and (5) K-strategists (Foley 1978; Henke and Rothe 1999). When reflecting on the possibilities of coping with the environment, and niche-separation, and -expansion, we have to encompass all kinds of “internal” influences like: body size, population dynamics, abilities of locomotion and “thinking,” life history strategies, behavior, and social system. Furthermore, the role of “external” factors such as climate, biogeography, sympatric species, and predator–prey relationships have to be taken into account (Foley 1978).

### Table 17.6

</tbody>
</table>

Compiled after Vrba 1988; Potts 1998.
About 2.0 Ma, several kinds of hominids settled in north western Kenya and south Ethiopia around Lake Turkana (Tattersall 2002): *Paranthropus boisei*, *P. (Australopithecus) aethiopicus*, *H. (Kenyanthropus) rudolfensis*, *H. (Australopithecus) habilis*, *H. erectus (ergaster)*; the genera and species names in parentheses indicate that the debate about their taxonomic status is still in progress. The Turkana Basin (Figure 17.3), situated in the Great Rift Valley from southern Ethiopia into northern Kenya, covers an area of about 3,600 km$^2$ and represents one of the richest fossiliferous areas in Africa. An exceptional breadth of “mosaic-like” geological and environmental diversity has been investigated by the Koobi Fora Research Project. It reaches from the lacustrine/fluvial sediments of the Omo river channel with gallery forests and swamps, across thorn bush and grassy floodplains strongly influenced by seasonal flooding, to the basin margins with an arid climate and totally different sedimentation regimes (kfpr.com/prehistory_of_koobi_fora). The geological record provides volcanic tephra layers, amenable to chronometric dating, that are associated with unusually well preserved fossils. The faunal record has a nearly gapless temporal as well as a lateral component, making it possible to reconstruct paleohabitats over large areas. The archeological remains include Oldowan, Karari, and Acheulian tools that complement the evidence of the fossil hominins.

The Omo basin sediments, fossils, and pollen provide a wealth of information about the ecological circumstances and the temporal distribution of hominids in this region. *P. boisei* and *P. aethiopicus* are strongly adapted to drier conditions in savannah habitats with gallery-forests or patchy wooden refugia. Craniodental morphology and especially microdental analyses suggest an exclusively low-quality herbivorous subsistence with sometimes coarse gramineous parts, dependent on the availability of food in a highly variable seasonal environment that is characterized by both copiousness and scarcity (Rak 1983; Foley 1987; Kay and Grine 1988; Henke and Rothe 1999). In contrast, gracile australopithecines seem to have preferred more humid habitats with large spots of forest (Coppens 2002) and were able to accommodate to substantial environmental variability and dietary shifts (Teaford and Ungar 2000; Bonnefille et al. 2004).

The most widely studied habitat-specific hypothesis is the savannah hypothesis. Dart (1925) already used the open savannah-model as a tool to explain larger brains and bipedality in early *Homo*. This concept plausible prima facie was not confirmed by the data collected (Leakey and Hay 1979; Cerling 1992; Senut et al. 2001): bipedalism was apparently established million years before the savannah grassland expansion. Early *Homo* lived in fairly open, arid habitats, used an enlarged spectrum of food resources, and is best characterized as an opportunistic and omnivorous forager. Basic sustenance was surely provided by plant food,
but the use of tools made accessible difficult-to-reach high-energy sources like edaphic storage organs (tubers and roots) (Laden and Wrangham 2005), and meat from scavenging complemented their diet (Foley 1987; Blumenschine et al. 1994). This latter is important when looking at coevolutionary processes and sympatric interdependencies between early Homo, herbivores, and carnivores (Turner 1984; Lewis 1997; Brantingham 1998). High-energy-density diets and unstructured feeding patterns (originated by the seasonal availability) still characterize present-day human eating behaviors, although today’s nutrition is largely uncoupled from seasonal cycles (Ulijaszek 2002). Hunting, as Lee and DeVore (1968) suggested, is widely accepted as unlikely in early Homo; it seems that the conception of a klepto-parasite seems to best characterize the real natural situation. Comparative primatological studies of chimpanzee populations and analyses of behavioral ecology and nutrition strategies in current African hunter-gatherer tribes (Lupo 2002; Marlowe 2005) support these assumptions. Vrba (1988 p 422) stated that “... in some respects the Homo lineage evolved toward a greater ecological generalization, while in contrast the ‘robust’ lineage(s) became more specialized on resources prevalent in more open environments.”

In the Middle and Late Pleistocene, the diversity of hominids decreased drastically, the “robust” australopithecines became extinct (Klein 1988) and Homo constituted the only remaining genus in the bottleneck of hominid evolution. The questions of how and why that happened and what processes were involved are manifold (Henke and Rothe 1999; Tattersall 2002; Rightmire Volume 3 Chapter 12).

17.4.3 Late phase: Neanderthals and colonizers

As one of the most discussed topics in human evolution, the Neanderthal enigma is a prominent “problem” of the late phase. d’Errico and Sánchez Goñi (2003) investigated the millennial scale climatic variability of OIS3 in the context of Neanderthal extinction. To the extent that population models seek climate as a triggering factor for the colonization of Europe by anatomically modern humans and the Neanderthal extinction, they appear to be highly contradictory due to (1) the lack of terrestrial continuous and well-dated paleoclimatic sequences, (2) uncertainties in the dating methods, and (3) the doubts about the cultural attribution of archeological layers. These authors therefore reviewed the paleoclimatic OIS3-evidence from Iberia and found a fragmentary, low-resolution, and ill-interpreted record. d’Errico and Sánchez Goñi (2003) concluded that Aurignacian moderns colonized the north of Iberia and France at the onset of the H4 event.
They based their results on a correlation between archeological data from Western Europe and from two IMAGES pollen-rich deep-sea cores. Their scenario favors Neanderthal populations existing in desert-steppe-like environments (made up of *Artemisia*, Chenopodiaceae, and *Ephedra* which characterize the H4 of this area), while the Aurignacian moderns were probably not interested in colonizing these arid Mediterranean biotopes. Anatomically modern humans did this only after the H4 event.

However, Finlayson et al. (2004) pointed out problems with this scenario. They admit that d’Errico and Sánchez Goñi’s (2003) paper is very useful in reinforcing the data showing that climatic events worldwide became increasingly unstable during OIS3, but as inferred by Finlayson et al. (2004 p 1208), there are problems of cause and effect: “We suggest that this is a spurious correlation and that what are being observed are two populations responding to the same variable (or variables) in opposite directions. Since no direct proof of cause and effect between Aurignacians and Neanderthals is advanced, this must remain the most parsimonious explanation.” Finally, they interpret d’Errico and Sánchez Goñi’s (2003) data in the opposite way by concluding that the available information points to climate instability fragmenting Neanderthal populations and emphasizing that not a single piece of evidence exists that demonstrates a competition between Moderns and Neanderthals.

Further questions we have to answer when discussing anatomically modern humans in Eurasia, Australasia, and the New World are: *Why and when did the expansion happen? Who and how many participated and where did they arrive?* Figure 17.12 provides an overview of potential migration waves and the time they probably took place. One consensus seems to crystallize from the fossil record: equipped with a stature shape and size near to ours (Turkana-boy from Nariokotome), large brain, increased mobility, handling hunting weapons (400–ka-old spears of Schöningen/Germany) as well as fire, and being provided with a significant curiosity, *H. erectus* (*H. ergaster*) migrated far from the continent of its birth at around 1.8 Ma (Dmanisi fossils) (Gabunia et al. 2001) and conquered the Old World. Thenceforward there are diverse models/hypotheses that try to explain dispersal patterns over the last 1.5 Myr of human evolution. The recent african origin model (RAO) holds that the biocultural transition from late archaic *H. sapiens* to anatomically modern humans was restricted to Africa, with subsequent dispersion and replacement of *H. erectus* ca. 200 ka. Another hypothesis assumes an anagenetic transition from the early hominines to *H. erectus*, (earlier than 1.5 Ma) followed by dispersal. In the view of Templeton (2002), second and a third expansion (Out-of-Africa “again and again”) shaped the modern human gene pool. The assumption that
H. sapiens developed independently and in parallel in several regions of the world is mainly based on Asian fossils (e.g., Zhoukoudian, upper cave) and is summarized as the “Multiregional continuity model,” or the polyphyletic hypothesis, with gene flow maintaining some genetic homogeneity (Wolpoff 1999, 2002). The “mostly Out-of-Africa hypothesis” (Relethford 1998, 2001) is a combination of the African replacement model with the multiregional model. All these hypotheses involve questions of whether migrating hominines replaced local populations or if they interbred (for further discussions see also Bräuer Volume 3 Chapter 14).

Referring to the questions we formulated at the beginning of this section, we want to add a third one: how did hominines migrate from Africa? In the early phase, hominids seem to have been restricted to certain African habitats (although there were relatively large numbers of “intra-African” dispersals [Strait and Wood 1999]); this restriction lapsed through the Pleistocene and hominids seemed to become more eurytopic and thus became able to tolerate a wider range of conditions (Foley 1978; Vrba 1995, 1999; Lahr and Foley 1998). It is possible to
see an ecological patterning in the colonization of temperate regions even when looking at the range of other species (mostly large mammals) that spread out of Africa alongside the hominids (Turner 1984; Lewis 1997; Brantingham 1998; Strait and Wood 1999). Certain characteristics of large mammals provide the capacity to exploit new environments, including (1) large body size, (2) carnivorous behavior, and (3) sociality in larger groups. Hence, we have to think about the general principles that encourage zoogeographic mobility (Foley 1987; Henke and Rothe 1999):

- **Carnivores** are more eurytopic than herbivores. Meat requires less specialized and locally restricted adaptations than plants, thus carnivores are expected to migrate faster than herbivores, which are restricted to specific plants in a specific area.
- **Exogeny**: the attribute of an organism to forage across a variety of niches, giving it higher tolerance, less specialization, increased interspecific competition.
- **Environmental physiology**: Increasing body size enhances the energetic situation of an organism in terms of the relation between body weight and surface (Bergmann’s rule 1847; Aiello and Wells 2002). Consequently, larger mammals are able to cope more efficiently with temperate conditions. The extremities tend to be reduced in colder environments to diminish frostbite as seen in the distal limb segments of Neanderthals (Allen’s rule 1906). “There is indeed some possibility that the increase in body size associated with *Homo erectus* [. . .] may have at least contributed to the success of human geographical spread” (Foley 1987 p 268).

Additionally, home range size and diet quality seem to be closely related to initial dispersals from Africa (Antón et al. 2002). Although these principles are able to account for the expansion of early hominines, certain problems related to surviving high latitude habitats remain: (1) resource availability is highly seasonal and (2) the annual variation in day length shortens the time for foraging and other activities in winter. Favored strategies here are the extraction of resources yielding high returns and an increase in the efficiency with which resources are extracted. The former is linked to an increase in carnivory and high-energy food, the latter to increasing predatory efficiency and, especially in hominines, improved tool-manufacturing and -using. Additionally, producing complex and efficient stone tools demands advanced cognitive competence and accordingly constitutes an interaction between encephalization and culture (Klein 2000; Wynn 2002; Osvath and Gärdensfors 2005; Biagi Volume 1 Chapter 24; Toth and Schick Volume 3 Chapter 21). Most likely, habitat structure and resource
types were the driving forces that mainly influenced dispersals and the sequence of habitat colonization by hominids (Foley 1987).

17.5 Conclusions

Human evolution is not a “Sonderweg” (exceptional way); it follows strictly the rules of evolutionary biology and constitutes neither a special case nor determines the terminal branch-end in the Tree of Life, let alone creation’s crowning glory (Foley 1978, 2002). It is just the story of balanced interrelationships between environment and large mammalian genera possessing preadaptations that facilitated coping with the conditions during a specific time span. Corresponding to Foley (2002), we assume that the following key events altered the direction of radiations and dispersals in the hominid lineage:

1. Invasion of Africa from Asia of an ancestral lineage of Miocene primates and the outcome of African apes, and “hominids” *Ardipithecus, Orrorin*, and *Sahelanthropus*;
3. Megadonty and masticatory-apparatus increase as adaptation to low-quality nutrition in a mosaic-like environment in the “robust” australopithecines (taxa: *P. (A.) aethiopicus, P. (A.) boisei, P. (A.) robustus*) during the latest Pliocene and Early Pleistocene;
4. Radiation of earliest *Homo* is the most problematic of all because the phylogenetic position is extremely uncertain and variation within the group extensive (taxa: *Kenyanthropus platyops, H. (K.) rudolfensis, H. habilis*). Nevertheless, there is a clear hint toward a trend: brain size increase;
5. The diversification and dispersal of *Homo* 1.75 Ma (taxa: *H. erectus, H. ergaster*) and a second radiation of later forms of *Homo* 0.5 Ma (*H. heidelbergensis*), bound to several changes in dental/cranial morphology and behavior (carnivory, hunting, tradigenesis), the development of technologies (stone tools), and the usage of fire;
6. Enhanced neural capabilities and improvement of lithic and hunting technologies (e.g., projectiles) in the context of interglacial/glacial cycles may have led to repeated dispersals following each other with the outcome of *H. neanderthalensis* and *H. sapiens*;
7. Symbolic thought combined with language and the opening of new resources (e.g., aquatic food) characterizes the radiation and global colonization of *H. sapiens* in the last 100 kyr. Why and how the Neanderthals became extinct is still a matter of debate;

8. Recently, humans seem to have detached themselves from selection-pressures (except regarding their own species and some kinds of pathogens). This, however, brings with it great responsibility to safeguard the global ecosystem and thus to afford further evolutionary development.

We would like to stress that primate and consequently hominid evolution is a complex process that has to be seen from different angles and needs all of the different scientific approaches currently available.

One question remains open: *Is paleoecology an adequate window on the past?* We answer that in the affirmative but, as in any other hypothesis-based scientific field, we realize that without paying attention to possible pitfalls and without interpreting the results in context, we are in danger of simply telling stories. Unfortunately, there are no “laws” in ecological science such as exist in chemistry and physics; there are merely a lot of hypotheses that have to be tested and one concept that is close to a “law”: natural selection (Pianka 1983). Hence, we conclude that paleoecology—when conceived with care—is an important field of evolutionary biological, and especially of paleoanthropological, research. When discussing hominid evolution, and consequently our own evolutionary history, the danger of storytelling is potentially higher because fossils are rare, sample biases high, and not least because hypotheses always stand on shaky ground when the subject is ourselves (White 2000).

Actualism may be a path that leads to “true” inferences when ecological models and model-organisms are selected carefully. For example, *Pan*, as our genetically-closest relative, seems to be a good model from which to derive inferences, but as a restricted occupant of dense and humid forest habitats with significant morphological adaptations it might not be the first choice for reconstructing the selective pressures that affected early humans living “on the edge” between open and closed habitats (see also Susman and Hart Volume 1 Chapter 23).

It is obvious that paleoecology demands a multidisciplinary approach. However, nearly all researchers are specialized in their own “scientific niches” and struggle to keep and defend them. The great challenge ought to be the creation of a “scientific biocenosis” that helps us to understand evolutionary processes in terms of all the phenomena we are able to examine. The “scientific environment,” however, is sometimes harsh, and chilly winds blow sharp waving the banner of publication amount and impact factor. We would hope, although, that a high
adaptational species—such as ourselves—could change and improve this “habi-
tat” to enhance the “ecology” of pure science.

Acknowledgments

Thanks to Ian Tattersall and Winfried Henke, first for inviting us to contribute to their extraordinary compendium, second for encouragement, and last but not least for proofreading; Hartmut Rothe for initiating the conception of this Handbook; Holger Herlyn and Uwe Hoßfeld for useful ideas on literature and citation.

Abstract

Stable isotope ratio analysis is now regularly used to investigate early hominin diets based on the principle that “you are what you eat.” Analysis of collagen from Neanderthals and anatomically modern humans prior to 20 ka has shown them to be significantly enriched in $^{15}$N compared to contemporaneous carnivores and herbivores. This suggests that animal foods were a dominant component of their diets, although it must be borne in mind that collagen $\delta^{15}$N can underemphasize the importance of plant foods. Carbon isotope analysis of the enamel mineral of South African australopiths and early Homo has revealed that these taxa consumed $\sim$30% C$_4$ foods such as tropical grasses, sedges, or animals that ate these foods. Moreover, the australopiths are characterized by remarkably variable $\delta^{13}$C values. Chimpanzees, in contrast, are nearly pure C$_3$ consumers even in environments with abundant C$_4$ vegetation. These data suggest that when confronted with increasingly open areas, chimpanzees continue to exploit the foods that are most abundant in forest environments, whereas australopiths utilized novel C$_4$ resources in addition to forest foods.

18.1 Introduction

The nature of early hominin diets has been the subject of lively debate, and not without good reason (Robinson 1954; Dart 1957; Jolly 1970; Binford 1981; Grine and Kay 1988; Sillen 1992; Lee-Thorp et al. 1994; Stiner 1994; Sponheimer and Lee-Thorp 1999a; Richards et al. 2000; Speth and Tchernov 2001). Most large primates spend at least 50% of their waking hours searching for or consuming food (Altmann and Altmann 1970; Teleki 1981; Goodall 1986). Thus, if we seek to know what “a day in the life” of our ancestors was like, understanding what they ate would represent an enormous step in that direction. Furthermore, diet is considered among the most important factors underlying behavioral and
ecological differences among extant primates (Ungar 1998; Fleagle 1999), and thus the story of our ancestors’ evolving diets is likely to be intertwined with that of how our species, *Homo sapiens*, came to be. We can glean paleodietary information from many sources. Archeological evidence in the form of stone tools and butchered animal bones is one source of dietary information, which tells us about the kinds of animals that hominins utilized as well as their procurement strategies (Binford 1981; Brain 1981; Blumenschine 1987; Stiner 1994; Speth and Tchernov 2001). Yet, such evidence tends to overemphasize the importance of animal foods at the expense of plant foods that make up the bulk of most primate diets (Lee 1979; Eaton and Konner 1985; Milton 2002). Moreover, the first potential hominins (Senut et al. 2001; Brunet et al. 2002; Haile-Selassie et al. 2004) precede the earliest archeological traces by millions of years (Semaw et al. 1997; De Heinzelin et al. 1999), and thus the archeological record remains silent with regard to the diets of the earliest hominins.

As a result, paleoanthropologists have had to look for other sources of paleodietary information. Dental allometry/morphology and microwear have received much attention and provided important insights into the diets of our ancestors (Robinson 1954; Grine 1981, 1986; Grine and Kay 1988; Ungar and Grine 1991; Teaford et al. 2002; Ungar 2004). Still, these techniques have limitations. For instance, the relatively large incisors and bunodont molars of modern *Papio* suggest a frugivorous diet (Hylander 1975; Ungar 1998; Fleagle 1999), and yet many *Papio* populations consume large quantities of grasses, for which they have no apparent dental specializations (Altmann and Altmann 1970; Harding 1976; Dunbar 1983; Strum 1987). Ungar (2004) has also argued that the dental morphology of extant apes and early hominins may tell us more about their fallback foods than it does about their “typical” diets. Dental microwear, in turn, reveals a great deal about the mechanical properties of a primate’s food. Primates that eat hard, brittle foods, such as gray-cheeked mangabeys (*Lophocebus albigena*), have relatively more microscopic pitting on their molars than do those that eat more pliant, tough foods like mountain gorillas (*Gorilla gorilla beringei*) (Grine and Kay 1988; Ungar 1998). However, microwear is quickly obliterated and therefore provides dietary information for a few brief days, which may or may not be representative of an individual’s “average” diet. In addition, soft foods, such as animal flesh, may not always produce recognizable microwear signatures. Thus, even with these important techniques in our paleodietary arsenal, a great deal about the diets of early hominins remains unknown.

Consequently, new paleodietary techniques have emerged in recent years, one of the most important of which is stable isotope analysis. The idea behind this technique is that “you are what you eat.” In other words, the isotopic composition of one’s food is ultimately traceable in one’s tissues. Thus, stable
isotope analysis provides a direct chemical means of investigating the diets of modern and fossil primates. In this chapter, we address the contribution of stable isotope analysis to our understanding of early hominin diets. This chapter is divided roughly into two sections: stable isotope analysis of bone and dentine collagen, which has been used to investigate the diets of our close cousins the Neanderthals and early modern humans (Bocherens et al. 1991, 1999, 2001, 2005; Fizet et al. 1995; Richards et al. 2000, 2001; Pettitt et al. 2003; Schulting et al. 2005), and stable isotope analysis of enamel apatite, which has shed much light on the diets of the South African australopiths and early Homo (Lee-Thorp et al. 1994, 2000; Sponheimer and Lee-Thorp 1999, 2003; van der Merwe et al. 2003; Sponheimer et al. 2005a). We proceed in this reverse chronological order in an effort to trace the general development of paleodietary stable isotope studies: collagen was first utilized in 1977 with enamel apatite studies appearing a decade later. In addition, the temporally and geographically restricted discussion herein (i.e., the emphasis on European Neanderthals and South African australopiths) is more a reflection of the limited degree to which stable isotopes have been used to investigate the diets of Plio-Pleistocene hominins than selective presentation on our part. The only data we have excluded for this chapter are for specimens younger than 20 ka. The stable isotope data for all older hominins, that we are aware of, at least, are discussed herein and can be found in Tables 18.1 and 18.2.

18.2 Using organic material

18.2.1 Collagen

The first paleodietary study using stable isotopes sought to document maize consumption among Native American populations in New York State (Vogel and van der Merwe 1977). This application was made possible by differences in the photosynthetic pathways of plants. Tropical grasses, such as maize, use C₄ photosynthesis, while virtually all other potential plant foods in New York State use C₃ photosynthesis. The C₃-photosynthetic pathway discriminates markedly against ¹³C, and as a consequence, C₃ plants have very depleted ¹³C/¹²C ratios. In contrast, plants that utilize the C₄-photosynthetic pathway discriminate less against ¹³C and are consequently relatively enriched in ¹³C (Smith and Epstein 1971; Figure 18.1). These distinct isotopic signatures are passed down into the tissues of individuals that eat these plants. Thus, individuals who eat large quantities of C₄ plants like maize will be relatively enriched in ¹³C compared to those who eat only C₃ vegetation. Vogel and van der Merwe (1977) analyzed
the bone collagen of individuals ranging in age from \(4,000\) BP to \(500\) BP. They saw little evidence of maize consumption among the oldest individuals but found that maize had become a very important dietary resource by about \(1,000\) BP—sometimes representing up to 50% of an individual’s diet. This study paved the way for a plethora of innovative applications in the following decades which relied on stable isotope abundances in bone collagen; however, since collagen is rarely preserved for more than 10,000 years, these investigations were largely confined to the recent past. Yet, recent studies have shown that, under the right conditions, bone collagen can survive for 200,000 years or more (Jones et al. 2001). Thus, it has proven possible analyze the bone collagen of Late Pleistocene hominins in certain cases.

### 18.2.2 Collagen: methodological considerations

Before proceeding to the hominin data, we will briefly discuss a few relevant methodological considerations. Much has changed since the early days of stable...

In the provenience column, site abbreviations (SK = Swartkrans, MAK = Makapansgat, ST = Sterkfontein, KB = Kromdraai B) are followed by the appropriate Member number.
isotope with. Today, only small samples are required for analysis, and automation has led to significantly increased sample throughput in laboratories around the world. Nevertheless, the basic procedures have remained largely the same, even though the protocols vary somewhat from laboratory to laboratory. Here, we briefly summarize the operational protocols of the laboratories that have analyzed the collagen of early hominins. One must keep in mind, however, that this is meant to be a general summary and not an exhaustive step-by-step explication of analytical procedures.

After surface cleaning bone or dentine samples are demineralized in dilute HCl (0.5–1.0 M) for periods ranging from 20 min to 5 days. Performing this step at low temperature (5°C) is one recent innovation that allows collagen to be extracted from very old, fragile samples (Richards and Hedges 1999; Jones et al. 2001). The insoluble residue may then be soaked in 0.125 N NaOH to remove contaminating humic acids, but as this leads to collagen solubilization and decreased extraction yields, it is no longer favored. Fortunately, neglecting this step appears to have little effect on the resulting stable isotope ratios (Bocherens et al. 1999). The residue is then often gelatinized in weak HCl at 75°C–100°C, filtered, and freeze-dried. A small (~1 mg) sample of this purified collagen is then combusted in an elemental analyzer and the resultant CO₂ and N₂ gases are analyzed for ¹³C/¹²C and ¹⁵N/¹⁴N abundances in a stable isotope ratio mass

---

Figure 18.1

¹³C/¹²C ratios of plants using C₃ (trees, bushes, shrubs, and forbs) and C₄ photosynthesis (grasses and some sedges) in Kruger National Park, South Africa. The boxes represent the 25th–75th percentiles (with the medians as horizontal lines) and the whiskers show the 10th–90th percentiles. The carbon isotope compositions of plants using these different photosynthetic pathways are highly distinct. Maize is a tropical grass that uses C₄ photosynthesis, and thus it has a very different carbon isotope composition than other foods that were consumed by Native Americans in New York State (Vogel and van der Merwe 1977)
spectrometer. Stable light isotope ratios are expressed as δ values in parts per thousand (‰) relative to international standards, which are Pee Dee Belemnite (PDB, a marine carbonate) and atmospheric N₂ for carbon and nitrogen, respectively. Standard deviations of replicate measurements are generally about ±0.1‰ for carbon and ±0.2‰ for nitrogen. Importantly, collagen degradation is known to alter stable isotope ratios significantly. Collagen must generally have a carbon/nitrogen ratio between 2.9 and 3.6, with carbon and nitrogen percentages of at least 15% and 5%, respectively, to produce reliable results (Ambrose 1990).

Our understanding of the relationship between dietary δ¹³C and collagen δ¹³C has improved significantly since the first use of stable isotopes for paleodietary reconstruction. Experimental studies of rodents on controlled diets have shown that collagen δ¹³C is enriched by about +5‰ relative to dietary protein (Ambrose and Norr 1993; Tieszen and Fagre 1993), as dietary amino acids are preferentially utilized for tissue synthesis. In contrast, carbon from dietary carbohydrate and lipid makes much less of a contribution to bone collagen (or indeed hair or muscle, etc.). Consequently, bone collagen δ¹³C (and δ¹⁵N) tells you more about the protein component of an individual’s diet than it does about their “whole” or “bulk” diet. This is significant, as animal foods which are high in protein will be overrepresented in bone collagen at the expense of low-protein vegetable foods. This bias must be borne in mind when interpreting collagen stable isotope data.

18.2.3 The Neanderthals

Bocherens et al. (1991) performed the first stable isotope analysis of a Neanderthal and associated fauna from the site of Marillac in France. This study demonstrated that enough collagen could be extracted from bones more than 40,000 years old, and paved the way for subsequent analyses of Neanderthals from Marillac and Saint-Cesaire (Fizet et al. 1995; Bocherens et al. 2005); Scladina Cave, Awirs Cave, and Betchelal-Roche Cave in Belgium (Bocherens et al. 1999; 2001), and Vindija Cave in Croatia (Richards et al. 2000). Virtually all native European plants use the C₃-photosynthetic pathway. As a result, these plants have similar carbon isotope compositions, although those in densely wooded environments are somewhat depleted in ¹³C due to the canopy effect (Vogel 1978; van der Merwe 1989). Thus, not surprisingly, carbon isotopes revealed little about the diets of Neanderthals, save for the possibility that they utilized few food resources from closed environments (Bocherens et al. 1999; Richards et al. 2000) (Table 18.1).

The nitrogen isotopes in Neanderthal bone collagen, however, proved more revealing. Nitrogen isotopes ratios (¹⁵N/¹⁴N) are known to increase by about 3‰
up every step in the food chain (Minagawa and Wada 1984; Schoeninger and DeNiro 1984; Ambrose and DeNiro 1986). Thus, within a hypothetical food web, if plants have $\delta^{15}N$ values of 0‰, herbivores like reindeer have $\delta^{15}N$ values of about 3‰, while carnivores, such as wolves, have $\delta^{15}N$ values of about 6‰. And although nitrogen isotope distributions in food webs are more complicated than this hypothetical example suggests—due to heterogeneity in plant $\delta^{15}N$ and the disparate physiological adaptations and requirements of mammals (Ambrose and DeNiro 1986; Sealy et al. 1987; Sponheimer et al. 2003a)—the general pattern has been shown to be robust in both terrestrial and marine ecosystems. Thus, analysis of nitrogen isotopes in bone collagen can potentially reveal the trophic level at which a hominin was feeding. This is relevant for investigating Neanderthal diets, as their degree of carnivory and manner of carcass acquisition (hunting or scavenging) have been the subject of considerable debate (Binford 1981; Mellars 1989; Stiner 1994; Speth and Tchernov 2001).

Intriguingly, all published studies have shown that Neanderthals have very high $\delta^{15}N$, well above that of contemporaneous herbivores, such as horses (Equus caballus), reindeer (Rangifer tarandus), and bison (Bison priscus), and similar to that of carnivorous wolves (Canis lupus), hyenas (Crocuta spelaea), and lions (Panthera spelaea) (Bocherens et al. 1991, 1997, 2001, 2005; Fizet et al. 1995; Richards et al. 2000). Indeed, analysis of variance and Fisher’s PLSD test of the combined datasets show that Neanderthal $\delta^{15}N (x = 10.9\%o, S.D. = 1.1, n = 12)$ is not only significantly higher than herbivore $\delta^{15}N (x = 5.8\%o, S.D. = 1.6, n = 132) (p < 0.001)$, but also slightly higher than carnivore $\delta^{15}N (x = 9.7\%o, S.D. = 1.1, n = 26) (p = 0.02)$ (Figure 18.2; Table 18.1). We should note that the combined dataset contains specimens that accumulated over ~70,000 years and in locations throughout Europe, and that such temporal and spatial mixing increases intrataxonomic variability making statistically significant differences between taxa less likely. For instance, Stevens and Hedges (2004) found that European horse (Equus spp.) $\delta^{15}N$ fluctuated by at least 4‰ over the last 40,000 years due to glacially mediated changes in the nitrogen cycle. Hence, it is particularly striking that significant differences are found between Neanderthals, herbivores, and carnivores without controlling for temporal and spatial variation. In general, the $\delta^{15}N$ data appear to suggest that Neanderthals were highly carnivorous and received little of their dietary protein from plant foods (Richards et al. 2000), despite the bias toward animal foods in bone collagen. Enrichment in $^{15}N$ compared to (other) carnivores may suggest a dependence on herbivores with relatively high $\delta^{15}N$, such as mammoths (Mammuthus primigenius), or even the consumption of omnivorous bears (Ursus spp.) (Richards et al. 2000; Bocherens et al. 2001, 2005). While interpretation of these data remains difficult, it is clear that Neanderthal diets were distinct from those of contemporary herbivorous fauna.
This leads inexorably to the question “Were Neanderthal diets distinct from those of their hominin contemporaries?” While it has not yet been possible to compare the stable isotope compositions of Neanderthals and contemporaneous anatomically modern humans (AMH), Richards et al. (2001) were able to analyze nine near-contemporaries from the mid-Upper Paleolithic (~28–20 ka) at Brno-Francouzska and Dolni Vestonice (Czech Republic); Kostenki, Mal’ta, and Sunghir (Russia); and Paviland (Great Britain). They compared these anatomically modern humans to the five Neanderthals that had been published at the time, and argued that the modern humans were even more elevated in $\delta^{15}N$ ($\bar{x} = 12.0\%o$, S.D. = 1.6, $n = 9$). This suggested that anatomically modern humans were also highly dependent on animal foods. Richards et al. (2001) argued, however, that even the consumption of high-$\delta^{15}N$ herbivores would not be sufficient to account for the extremely elevated $\delta^{15}N$ of these AMH. Instead, they suggested that these humans had begun to diversify their resource base to include freshwater aquatic resources, such as fish and waterfowl, which can be more enriched in $^{15}N$ than terrestrial resources (Dufour et al. 1999; Katzenberg and Weber 1999). This suggestion was rather surprising as there is little direct archeological evidence for exploitation of such foods at this time, although such evidence becomes abundant by the late Upper Paleolithic. Yet, with the subsequent publication of seven new Neanderthal specimens (Bocherens et al. 2001, 2005) and two more mid-Upper Paleolithic humans (Pettitt et al. 2003; Schulting et al. 2005), there is no longer any statistically significant difference in the $\delta^{15}N$ of AMH ($\bar{x} = 11.8\%o$, S.D. = 1.6, $n = 11$) and Neanderthals ($p = 0.06$)
t-test; \( p = 0.09 \) Mann–Whitney \( U \)) (Figure 18.3; Table 18.1). There is, however, a small, but significant difference in the \( \delta^{13}C \) of AMH (\( x = -18.7 \% \), S.D. = 0.5, \( n = 11 \)) and Neanderthals (\( x = -20.0 \% \), S.D. = 0.8, \( n = 12 \)) (\( p < 0.01 \) t-test and Mann–Whitney \( U \)), although the meaning of this difference is unclear. A greater reliance on open area resources, such as \(^{13}C\)-enriched reindeer, by AMH is one of many possible explanations. More salient from the perspective of dietary breadth, Levene’s test reveals no significant differences in the isotopic variability of Neanderthals and AMH (\( \delta^{13}C, p = 0.23; \delta^{15}N, p = 0.61 \)), and thus there is little isotopic support for the utilization of novel resources or greater resource breadth in AMH prior to 20 ka.

These stable isotope studies are an important complement to traditional archeological paleodietary studies as they represent a direct measure of the foods that an individual ate, which is independent of the taphonomic biases that bedevil faunal analyses (Lyman 1994). Nevertheless, interpretation of these stable isotope data is not straightforward, and there remain a number of important unanswered questions. For instance, why are both hominins enriched by more than 5\% compared to associated herbivores when an enrichment of about 3\% would be expected for a carnivore? Stated otherwise, why is their \( \delta^{15}N \) significantly higher than that of associated carnivores? As discussed earlier, this may be partially, but not satisfactorily, explained by the consumption of herbivores with...
unusually high $\delta^{15}N$, such as mammoths, or even by the consumption of omnivores and/or aquatic resources. Another possibility, however, is that there is some physiological explanation for their extremely high $\delta^{15}N$. Experimental studies have shown that when herbivores are fed diets with crude protein contents that are much greater than their nutritional requirements, their diet-tissue spacing can become much greater than $3\%$ (Sponheimer et al. 2003a). This implies that if the prevailing environment forced Neanderthals to consume high-protein diets that considerably exceeded their crude protein requirements, their diet-tissue spacing might have exceeded $3\%$, thus artificially increasing their $\delta^{15}N$ compared to other taxa. On the other hand, committed carnivores generally have smaller diet-tissue spacing than herbivores (Robbins et al. 2005). Regardless, the anomalously high $\delta^{15}N$ of mammoths and low $\delta^{15}N$ of cave bears (Bocherens et al. 1997; Ambrose 1998) may also hint at the importance of physiological adaptations in determining an organism’s nitrogen isotope composition.

It is worth noting that while such interpretive difficulties exist, they do not diminish the significance of these studies. Even if the Neanderthals did have artificially increased diet-tissue spacing due to a high-protein intake, it might erase their distinctiveness from other carnivores but would certainly not make them look herbivorous. Thus, there can be little doubt that Neanderthals consumed large quantities of animal foods.

### 18.3 Using inorganic material

#### 18.3.1 Enamel apatite

Older hominin material is not amenable to this form of analysis as bone collagen is rarely preserved from beyond the Late Pleistocene (Jones et al. 2001). However, the carbon isotopes in bone’s mineral component (a biological apatite) can also be used as dietary proxies (Sullivan and Krueger 1981, 1983; Lee-Thorp and van der Merwe 1987). But even though bone mineral clearly persists beyond bone collagen, it can be altered postmortem, often resulting in the loss of the biogenic dietary signal (Lee-Thorp and van der Merwe 1987; Wang and Cerling 1994; Lee-Thorp 2000). This is due to bone’s high organic content, porosity, and small crystal size, which make it susceptible to dissolution/reprecipitation phenomena and facilitates the incorporation of diagenetic carbonate ions (LeGeros 1991; Lee-Thorp 2000; Lee-Thorp and Sponheimer 2003). Thus, bioapatite paleodietary studies were forestalled until Lee-Thorp and van der Merwe (1987) showed that dental enamel from ancient fauna with well-understood diets retained its biogenic isotope signal. For example, they showed that fossil equids, like their
modern counterparts, had C$_4$-dominated signatures, while fossil tragelaphines had C$_3$-dominated signatures like their modern descendants. Since then, numerous empirical and theoretical studies have substantiated this finding (Lee-Thorp et al. 1989a; Wang and Cerling 1994; Sponheimer and Lee-Thorp 1999b; Hoppe et al. 2003; Lee-Thorp and Sponheimer 2003; Trickett et al. 2003). Enamel’s resistance to diagenetic phenomena is conferred by its virtually organic-free and highly crystalline state (LeGeros 1991), which renders it effectively “prefossilized.” Thus, tooth enamel offered the possibility of investigating the diets of Early Pleistocene and even Pliocene hominins.

18.3.2 Enamel bioapatite: methodological considerations

For the reasons outlined above, only tooth enamel is sampled for stable isotope analysis of hominin and non-hominin specimens that are millions of years old. Initially, a sample of 200–400 mg was needed (about half of a baboon’s molar), but advances in mass spectrometry have reduced the necessary sample size to a few milligrams (Lee-Thorp et al. 1997; Sponheimer 1999). As a result, it has become possible to sample teeth while producing little to no readily observable damage. As a result, more teeth have become available for analysis.

We will now give an overview of the recent sampling and pretreatment protocols, which are modified after Lee-Thorp et al. (1997) and Sponheimer (1999). Specimens are given a careful visual inspection prior to sampling, and those that are heavily stained or have mineral inclusions in the potential sampling areas are excluded from analysis. Generally, only permanent dentition is sampled, with a heavy emphasis on late forming teeth such as M$_2$s and M$_3$s. Powdered enamel samples are acquired (usually from a tooth’s buccal surface) using a low-speed rotary drill with a diamond-tipped burr. However, most of the recently sampled hominin teeth had been previously fractured, which allowed sampling between the occlusal surface and the enamel–dentine junction so as to avoid damage to the external surface of teeth. Although only small samples are taken (~2 mg), we generally attempt to sample over as extensive an area as is possible in order to obtain enamel formed over a considerable period of time. The enamel powder is then pretreated with 0.1 M acetic acid for ~10 min to remove diagenetic carbonates and rinsed to neutrality. This is followed with a ~10 min soak in 1.5% sodium hypochlorite to remove organic contaminants, after which the remaining enamel powder is rinsed to neutrality and freeze-dried. It is worth noting that these pretreatment protocols can vary from laboratory to laboratory, and even within laboratories over time. As different pretreatments can lead to
small but significant differences in a sample’s stable isotope composition (espe-
cially oxygen), one must compare stable isotope values for teeth analyzed follow-
ing different protocols with caution. Finally, each sample is placed in an
individual reaction vessel and analyzed for $^{13}$C/$^{12}$C and $^{18}$O/$^{16}$O using an auto-
carbonate device coupled to a stable isotope ratio mass spectrometer. Carbon and
oxygen isotope ratios are expressed as $\delta$ ($^{13}$C, $^{18}$O) values in parts per thousand
(‰) relative to the PDB standard. The standard deviations of replicate measure-
ments are typically 0.1‰ and 0.2‰ for $\delta^{13}$C and $\delta^{18}$O, respectively. Oxygen
isotopes do provide ecological information (Kohn et al. 1996; Sponheimer
and Lee-Thorp 1999c, 2001), although they are much better known as paleocli-
matic proxies (Prentice and Denton 1988; Ayliffe and Chivas 1990). For this
reason, and because of space constraints, we will not discuss them as paleoecolog-
ical indicators here.

The relationship between dietary $\delta^{13}$C and enamel apatite $\delta^{13}$C has been well
studied. Unlike collagen, apatite tends to reflect the $\delta^{13}$C of the “whole” or “bulk”
diet and not just the protein component (Ambrose and Norr 1993; Tieszen and
Fagre 1993). Thus, apatite and bone collagen $\delta^{13}$C provide different perspectives
on an individual’s diet. Indeed, if one wanted to obtain the most complete picture
of an individual’s diet, one should analyze both collagen and apatite, although
this rarely happens in practice. Most important of our purposes here, however, is
that enamel apatite provides a good average dietary signal and will equally reflect
the consumption of vegetable and animal foods. Yet, there, is evidence that the
relationship between dietary $\delta^{13}$C and apatite $\delta^{13}$C is not constant. Rodent
apatite tends to be enriched by about +10‰ compared to diet (Ambrose and
Norr 1993; Tieszen and Fagre 1993), while large mammal apatite is enriched by
about +13‰ (Lee-Thorp et al. 1989b; Cerling and Harris 1999; Passey et al.
2005). These differences must be borne in mind when comparing rodent and
nonrodent $\delta^{13}$C but are of little significance for the present discussion.

### 18.3.3 The australopiths and early Homo

As in the initial bone collagen study by Vogel and van der Merwe (1977), the
australopith studies were based on the distinct isotopic signatures of C$_3$ (trees,
bushes, shrubs, and forbs) and C$_4$ plants (tropical grasses and some sedges).
In the early 1990s, it was generally believed that Australopithecus africanus had a
diet of fleshy fruits and leaves, much like that of the modern chimpanzee (Pan
troglodytes), while Paranthropus robustus consumed more small, hard foods such
as nuts (Grine 1981, 1986; Grine and Kay 1988; Ungar and Grine 1991). As these
are all C$_3$ foods, one would then expect that Australopithecus and Paranthropus
would have $\delta^{13}C$ values indistinguishable from those of C$_3$ browsers and frugivores. Several studies have shown, however, that the $\delta^{13}C$ of both australopiths is very distinct from that of their C$_3$-consuming coevals (Lee-Thorp et al. 1994, 2000; Sponheimer and Lee-Thorp 1999a; van der Merwe et al. 2003; Sponheimer et al. 2005a).

**Figure 18.3** shows the combined australopith dataset from Makapansgat, Sterkfontein, Kromdraai, and Swartkrans, which now consists of 37 hominin specimens (Table 18.2). Analysis of variance and Fisher’s PLSD test show that both *Australopithecus* ($x = -7.1‰$, S.D. = 1.8, $n = 19$) and *Paranthropus* ($x = -7.6‰$, S.D. = 1.1, $n = 18$) are strongly different from contemporaneous C$_3$ ($x = -11.5‰$, S.D. = 1.3, $n = 61$) and C$_4$ consumers ($x = -0.6‰$, S.D. = 1.8, $n = 60$) ($p < 0.0001$), but cannot be distinguished from each other ($p = 0.18$). This distinction between the hominins and other fauna cannot be ascribed to diagenesis, as there is no evidence that browser or grazer $\delta^{13}C$ has been significantly altered, and diagenesis should affect hominins and nonhominin fauna alike. If we take the mean $\delta^{13}C$ of C$_4$- and C$_3$-consuming herbivores as indicative of pure C$_4$ and C$_3$ diets, respectively, this would indicate diets of about 35–40% C$_4$ vegetation for both *Australopithecus* and *Paranthropus*. Thus, both were eating considerable quantities of C$_4$ resources, possibly grasses, sedges, or animals that ate these plants. None of these possibilities were expected, as extant apes are not known to consume these foods to a significant degree (Goodall 1986; McGrew et al. 1982). Indeed, even in environments where C$_4$ foods are readily available, chimpanzee $\delta^{13}C$ does not indicate any C$_4$ consumption (Schoeninger et al. 1999; Carter 2001). This suggests a fundamental niche difference between the australopiths and extant apes, which is not so surprising given the vast differences in their craniodental morphology (Grine 1981; Kay 1985; Teaford et al. 2002; Ungar 2004).

It is worth noting that the evidence of extensive C$_4$ consumption was not the only surprise in the australopith dataset. Indeed, hominin $\delta^{13}C$ turned out to be more variable than virtually all modern and fossil taxa that have been analyzed in South Africa (Lee-Thorp et al. 1994, 2000; Sponheimer et al. 1999a, 2001, 2003b; Codron 2003; van der Merwe et al. 2003). There is considerable evidence that South African australopith habitats became more open between ~3.0 and ~1.7 Ma (Vrba 1980, 1985; Reed 1997; Luyt and Lee-Thorp 2003), and it might be argued that this environmental change forced the australopiths to modify their diets over time, leading to their unusually variable $\delta^{13}C$. Yet, linear regression demonstrates that there is no relationship between hominin $\delta^{13}C$ and time ($p = 0.63$, $R^2 = 0.01$; Figure 18.4), and there are no significant differences in hominin $\delta^{13}C$ between 3.0-Ma Makapansgat Member 3, 2.5-Ma Sterkfontein Member 4, or 1.8-Ma Swartkrans Member 1 (ANOVA, $p = 0.14$). Indeed, what
is most striking about these data is the lack of change in hominin δ\(^{13}\)C in the face of pronounced environmental change. Somewhat paradoxically, however, within any given time period (Member), hominin δ\(^{13}\)C is highly variable. This might simply indicate that the australopiths had wide habitat tolerances and always inhabited a similar range of microhabitats. This would be consistent with Wood and Strait’s (2004) recent suggestion that early hominins were eurytopic rather than ecological specialists.

In the case of *A. africanus*, the variability is so great that one might ask if there are not two ecologically distinct taxa presently commingled within its hypodigm. If one includes the numbers for three teeth (STW 236, STW 213i, STW 207) that are possibly, but not definitively, attributed to *A. africanus* (van der Merwe et al. 2003), then this taxon would range from nearly pure C\(_3\) to nearly pure C\(_4\) diets. Stated otherwise, the range of δ\(^{13}\)C within *A. africanus* (−1.8‰ to −11.3‰) would be nearly as great as the range for ecologically disparate *Papio* and *Theropithecus* combined (+0.4‰ to −12.6‰) (Lee-Thorp et al. 1989). Stable isotopes in and of themselves cannot address the question of *A. africanus* unity, but numerous researchers have suggested that *A. africanus* might demonstrate more morphological variability than would be expected for a single taxon (Kimbel and White 1988; Clarke 1994; Lockwood 1997; Moggi-Cecchi et al. 1998). Hence the possibility of two taxa, one subsisting largely on C\(_4\) foods and the other on C\(_3\) foods, cannot be dismissed.

So how do the australopiths compare with early *Homo*? Lee-Thorp et al. (2000) tested for isotopic differences between *Paranthropus* and rarer early *Homo*
specimens from Member 1 at Swartkrans. They assumed that if *Homo* consumed more animal foods, as was widely held, then its δ^{13}C values should be enriched compared to the australopiths because many savanna animals eat C_4 grasses. Surprisingly, though, *Homo* δ^{13}C was very similar to that of the australopiths and the results must be interpreted in a similar way: roughly 25% early *Homo*’s diet came from C_4 sources that included C_4 grasses, C_4 sedges, C_4-animal products, or some combination of these foods (Lee-Thorp et al. 2000). However, only three *Homo* specimens from one site have been analyzed and published, and thus comparisons with the more numerous australopith data must be viewed with caution. In fact, van der Merwe et al.’s (1999) unpublished carbon isotope data show a strong difference between East African *Paranthropus* and *Homo*, which serves to underscore the limitations of the currently published dataset. For this reason, the ensuing discussion will focus exclusively on the australopith data.

### 18.3.4 Which C_4 foods?

Which C_4 foods did the australopiths utilize? This question is quite significant, as use of these different resources might have a variety of physiological, social, and behavioral implications. For instance, if australopiths had a grass-based diet similar to that of the modern gelada baboon (*Theropithecus gelada*), this would almost certainly indicate that their diets were less nutrient-dense than those of modern apes, possibly placing important limitations on burgeoning hominin brains and sociality (Aiello and Wheeler 1995; Milton 1999). The converse, that australopiths ate diets rich in animal foods, would indicate a leap in dietary quality over modern apes which could have been a crucial step toward hominin encephalization, the development of stone tool industries, and increased social complexity (Milton 1999). Similarly, it has been suggested that consuming the underground storage organs of plants like C_4 sedges would represent an increase in dietary quality over that of extant great apes because they are lower in dietary fiber than ape fallback foods (Conklin-Brittain et al. 2002). We will now discuss the evidence for the consumption of C_4 grasses, C_4 sedges, and animal foods in turn.

#### 18.3.4.1 The case for grasses

Some researchers noted that the robust craniodental anatomy of the australopiths might have been an adaptation for eating grass seeds and roots as do modern gelada baboons (*T. gelada*) (Jolly 1970; Wolpoff 1973). A dental microwear study
of modern geladas showed that their molar microwear is dominated by scratches with little evidence of pitting (Teaford 1992), however, which is quite unlike the heavily pitted molars of the australopiths (Grine 1986; Grine and Kay 1988). This result is hardly surprising, though, as it would seem unlikely that relatively large-brained hominins could be sustained on gelada-like diet (high in fiber, low in protein, and long chain polyunsaturated fatty acids) without supplementation with higher quality foods. Furthermore, the stable isotope results do not indicate a pure C₄ diet, but rather one in which C₄ foods are very important and not exclusive. Therefore, even if the C₄ component did originate from grasses, one would not expect australopiths to have Theropithecus-like microwear.

One might expect, however, that australopiths and savanna baboon populations that consume large quantities of grass seasonally would show similarities in dental microwear (Altmann and Altmann 1970; Harding 1976; Dunbar 1983; Strum 1987), and indeed two recent studies of Papio molar microwear noted a more australopith-like frequency of pitting than was found in Theropithecus (Daegling and Grine 1999; Nystrom et al. 2004). In addition, a recent elemental analysis of australopithecus tooth enamel showed that while Australopithecus, and to a lesser extent Paranthropus, had higher Sr/Ca ratios than carnivores, browsers, and papionins, their Sr/Ca was quite similar to grazers. In fact, the unusual combination of high Sr/Ca and low Ba/Ca in Australopithecus has only been found in modern fauna that heavily utilize the underground portions of grasses such as warthogs (Phacochoerus africanus) and African mole rats (Cryptomys hottentotus) (Sponheimer et al. 2005b). These elemental data are still preliminary and certainly cannot be used to state affirmatively that early hominins consumed grasses. Nevertheless, they are entirely consistent with the possibility, and suggest avenues for future research.

18.3.4.2 The case for sedges

Sedges have also received attention as a potential C₄ food for australopiths. Conklin-Brittain et al. (2002) argued that a trend toward desiccation in the Pliocene eroded forests and ultimately forced australopiths into new, more open habitats. Although the degree, manner, and timing of this deterioration are a matter of some debate, the fact that it occurred is not (Vrba 1985; deMenocal 1995; Feibel 1997). Conklin-Brittain et al. (2002) reasoned that this loss of forest habitat forced australopiths into environments that were most similar to their ancestral forest homes, namely wetlands, swamps, and river margins. Sedges are readily available in these environments and have been argued to be among the possible
sources of the C\textsubscript{4} signal in australopiths (Sponheimer and Lee-Thorp 1999a; Conklin-Brittain et al. 2002). Some sedges have underground storage organs that have protein levels equal to those of most chimpanzee foods (9% crude protein) but much lower fiber levels (16% fiber) than foods consumed by chimpanzees (33%) (Conklin-Brittain et al. 2002). Thus, the regular inclusion of sedges in australopith diets might represent an increase in dietary quality over extant great apes. Equally important, the underground portions of sedges would be relatively inaccessible to most mammals, yet readily accessible to hominins with crude-digging implements (Hatley and Kappelman 1980), making sedges a high-quality resource for which there is very little competition. Such foods might have been particularly important during the dry season when other preferred dietary resources were scarce. Moreover, there is evidence of humans and other primates consuming sedges. Modern humans have consumed sedges like *Cyperus esculentus* and *Cyperus papyrus* for thousands of years (Tackholm and Drar 1973; Defelice 2002). Western lowland gorillas (*Gorilla gorilla gorilla*) have also been observed consuming the pith of sedges, although in small quantities (Doran and McNeilage 1998). Finally, *Australopithecus*’ high Sr/Ca is consistent with the consumption of sedge USOs (Sillen et al. 1995; Sponheimer et al. 2005b), although as previously mentioned, this is also consistent with the consumption of grass USOs.

But how likely is it that the observed C\textsubscript{4} signal in early hominins was derived from C\textsubscript{4} sedges? Although 33% of the world’s sedges use the C\textsubscript{4}-photosynthetic pathway (Sage et al. 1999), it is incorrect to assume that all or even most sedges available to australopiths would have utilized the C\textsubscript{4} pathway. Although 65% of Kenyan sedges reportedly use C\textsubscript{4} photosynthesis (Hesla et al. 1982), only 35% do in South Africa (Stock et al. 2004). More to the point, a study of sedges in riverine habitats similar to those inhabited by australopiths found that only 28% use C\textsubscript{4} photosynthesis (Sponheimer et al. 2005a). Thus, unless the South African australopiths deliberately sought out C\textsubscript{4} sedges, or the distribution of sedges was markedly different during the Pliocene, the australopiths would have had to have had a diet of 100% sedges to come close to producing the observed 35–40% C\textsubscript{4} signal. A slightly more probable scenario than this extreme sedge specialization is that the australopiths deliberately sought out C\textsubscript{4} sedges with particularly well-developed rootstocks such as *C. papyrus*, and thus a diet of 35–40% sedges would have been sufficient to explain the australopith carbon isotope values. Yet, this too is unlikely, for although these highly edible sedges are common in extensive perennial wetlands like the Okavango Delta, they are rare in the woodland/bushland habitats that were inhabited by australopiths (Reed 1997; Peters and Vogel 2005).
All told, the available data suggest that even if sedges did constitute an important resource for early hominins, they were likely supplemented with other C4 foods. It is worth noting, however, that some early hominin habitats in East Africa, such as the wetlands of the Eastern Lacustrine Plain at Olduvai Gorge (Hay 1976; Deocampo et al. 2002), might have been better sources of edible C4 sedges. The extremely enriched δ13C of *Paranthropus boisei* might indicate that C4 sedges were locally abundant and heavily utilized (van der Merwe et al. 1999). Puech et al. (1986) have also suggested that the dental microwear of early East African hominins is consistent with the consumption of such foods.

### 18.3.4.3 The case for animal foods

Animal foods can mean many different things including large and small vertebrates, invertebrates, and even birds’ eggs. These foods can also be acquired in a variety of ways including active hunting of large game, passive scavenging, and gathering of insects and eggs. Although chimpanzees are known to hunt a variety of small vertebrates such as red colubus monkeys (*Piliocolobus badius*) and blue duiker (*Cephalophus monticola*), these are pure C3 consumers (Teleki 1981; Goodall 1986). Therefore, intake of these foods could not contribute to the C4 component of australopith diets. More likely sources of the reported C4 signal include small grass-eating taxa such as hyraxes (*Procavia* spp.) and cane rats (*Thryonomys swinderianus*). The young of larger species would also be tempting targets. For instance, the young of antelope like reedbuck (*Redunca arundinum*) lie hidden and largely helpless for the first several months of life, making them easy prey for enterprising hominins.

Arthropods are also potential C4 foods. Baboons are known to eat grass-eating grasshoppers (*Acrididae*) almost exclusively during temporary gluts (Hamilton 1987). Grass-eating termites represent another intriguing possibility, particularly given recent studies suggesting that bone tools from Swartkrans were used to extract termites from mounds (Backwell and d’Errico 2001). Stable isotope studies of termites in African savanna environments have shown that they could have contributed to the australopiths’ 13C enrichment (Boutton et al. 1983; Sponheimer et al. 2005a). While termites range from nearly pure C3 to pure C4 consumers, the vast majority of savanna termites, even in densely wooded riverine microhabitats, consume significant proportions of C4 foods. In fact, termites throughout Krugerp National Park eat 35% C4 vegetation on average (Sponheimer et al. 2005a) (Figure 18.5). Thus, termite consumption by australopiths in woodland savanna and even in riverine forest would be expected to
impart some C₄ carbon to consumers. On the other hand, the fact that so few termites have a pure C₄ signal makes it unlikely that termite consumption alone was the source of the strong C₄ signal of australopiths, because it would require a diet of nearly 100% termites. Alternatively, if the hominins selectively preyed upon grass-specialist harvester termites (*Trinervitermes*, *Hodotermes*) with virtually pure C₄ diets, a diet of about 35–40% termites would be sufficient to produce the observed hominin carbon isotope ratios. This scenario, however, is highly unlikely because these C₄ termites are much less common than those with mixed C₃/C₄ diets in woodlands today; and while harvester termites are more abundant in open grasslands and during acute droughts (Braack and Kryger 2003), there is no reason to believe that australopiths frequented such open environments or that drought conditions were so preponderant. Moreover, while *Trinervitermes* builds highly visible above ground nests (mounds), *Hodotermes* does not, making it much less conspicuous on the landscape (Carruthers 1997; Stuart and Stuart 2000). Thus, it is possible and even likely that termites contributed in some way to the unusual δ¹³C values of australopiths, but other C₄ resources were almost certainly consumed in considerable quantities.

It has been suggested that hominid dental anatomy was not well-suited for the processing of animal foods (Teaford et al. 2002), but this observation only pertains to a limited class of animal foods. A great many animal foods require little, if any, oral processing. Termites, grasshoppers, ants, grubs, eggs, and a variety of other insect delicacies may be consumed whole, and even small vertebrates can be swallowed whole or in a few pieces (Smithers 1983). Brains, marrow,
and other soft tissues can also be consumed without oral processing. In addition, no experiments have been conducted to investigate the actual oral and/or pre-oral processing necessary to consume the muscle tissue of small vertebrates. Thus, it seems unwise to unduly limit the potential foods for australopiths until such studies have been undertaken. Furthermore, consumption of animal foods is common among mammals without seemingly appropriate dentition. One obvious example is the aardwolf (Proteles cristatus), which consumes hundreds of thousands of termites per night with largely nonfunctional, obsolescent dentition (Smithers 1983). In some cases this apparent disjunction between dental morphology and trophic behavior might result from the dentition being adapted for other, more mechanically challenging foods in an animal’s diet. For example, capuchin monkeys (Cebus apella) have large, bunodont dentition with thick enamel adapted for consuming fruits and hard nuts. Nonetheless, up to 50% of capuchin diets can come from animal foods, although the average is closer to 25% (Rosenberger and Kinzey 1972; Rosenberger 1992; Fleagle 1999). Similarly, Ungar (2004) has argued that among hominoids, differences in dental morphology primarily reflect their multifarious fallback foods rather than their preferred foods during times of plenty.

18.3.5 What does it mean?

All told, we still cannot be certain which C₄ resources were utilized by australopiths. Grass roots, grasshoppers, bird’s eggs, lizards, rodents, and young antelope might have been important C₄ resources, particularly during the dry season when little other food was readily available. Succulent plants like euphorbias (Euphorbiaceae) and aloes (Aloaceae) (which are rare in most woodlands but have δ¹³C values that are sometimes indistinguishable from those of C₄ grasses) are also possibilities; for although they are often poisonous to humans (and presumably chimpanzees), they are occasionally utilized by baboons and humans (Codron 2003; Peters and Vogel 2005). Further work on dental microwear and morphology, elemental analysis, and the potential availability and nutritional properties of foods may make it possible to identify these C₄ resources with greater confidence. At present, however, it seems likely that australopiths utilized a wide variety of these foods.

Despite this uncertainty, we should not lose sight of the most significant aspect of these stable isotope data, namely that australopiths increased their dietary breadth compared to extant apes by consuming novel C₄ resources, regardless of what these resources were. Similar evidence for increased dietary breadth is
also evident in their thicker enamel, larger postcanine dentition, and greater mandibular corpus robusticity, all of which point to the consumption of hard objects beyond the capabilities of extant apes (Teaford et al. 2002). Thus, the fundamental trophic difference between australopiths and extant apes might be that when confronted with increasingly open areas, apes continue to exploit the foods that are most abundant in forest environments (McGrew et al. 1982), whereas australopiths utilized novel C4 resources in addition to forest foods. There would have been a number of advantages to such a dietary strategy. It would have allowed australopiths to survive and even thrive in a much greater variety of habitats than do modern great apes, potentially allowing expansion of their range. Similarly, the increased dietary breadth could have buffered australopiths against climatic change and habitat loss. Another implication of increased dietary flexibility might be decreased foraging time and mobility, allowing for increased social interaction and possibly greater social complexity. This flexibility could also have increased dietary quality over that of extant apes by adding low-fiber underground storage organs and protein- and lipid-rich animal foods to australopith menus. This might have been an important step leading to greater encephalization and development of the genus Homo (Aiello and Wheeler 1995; Milton 1999; Conklin-Brittain et al. 2002).

If increased dietary breadth was a fundamental australopith adaptation, what are we to make of the later robust australopiths (Paranthropus robustus and Paranthropus boisei) in which the dental adaptations reached their most specialized form? They are believed to have been specialist hard object feeders that were eventually replaced by our Homo forebears who, for the first time, had regular access to higher quality animal foods (Aiello and Wheeler 1995; Milton 1999). An alternative explanation, however, is that the robust australopithecines were the quintessence of the trend toward dietary diversity because they could access the foods of their progenitors as well as harder foods. One might then argue that they were supplanted by Homo not because they ate different kinds of foods but because Homo was more efficient at procuring these resources due to increased use of extra-oral processing (e.g., stone tools) and greater planning depth. It is believed, for instance, that early Homo increased access to bone marrow from scavenged or hunted carcasses of medium to large mammals by using stone tools (Blumenschine 1987), whereas there is debate as to whether or not robust australopiths utilized such technology (Leakey et al. 1964; Susman 1988; Semaw et al. 1997; de Heinzelin et al. 1999). Furthermore, where australopiths may have eaten antelope lambs only when they stumbled upon them, Homo may have had superior planning depth and followed female antelope back to their young, capturing them only when the mother left once more.
18.4 Conclusions

Stable isotope studies have made an important contribution to our understanding of early hominin diets. In the case of Neanderthals, stable isotopes strongly support the contention that they were highly carnivorous, primary predators. As for the australopiths, stable isotopes suggest that they broadened the ancestral ape resource base to include C_4 foods, which coupled with bipedalism, allowed them to pioneer increasingly open and seasonal environments. Yet, as is the case with all paleodietary techniques, stable isotopes leave a great many important questions unresolved. Particularly important are the equifinality problems that are common in stable isotope studies. In other words, many different diets can lead to the same stable isotope signature. For instance, carbon isotopes often cannot distinguish between diets as different as folivory, frugivory, and carnivory. And although some progress has been made using oxygen isotopes to break such equifinalities (Sponheimer and Lee-Thorp 1999c; Carter 2001), there is little reason to believe that this problem can be entirely circumvented. In the end, stable isotopes are one tool among many, all of which provide a slightly different window into the diets of our ancestors. Thus, where stable isotopes cannot determine the favored prey of Neanderthals, faunal analysis has much to contribute (Speth and Tchernov 2001), and when carbon isotopes remain silent on the topic of australopith fallback foods, dental morphology may jump fruitfully into the fray (Ungar 2004). Thus, stable isotopes will prove most informative when pursued as part of a larger, integrated paleodietary investigation.

That being said, stable isotopes themselves still have a great deal to tell us about the diets of our ancestors. To date, only South African australopiths, Neanderthals, and AMH have been analyzed for stable isotopes to any significant extent, leaving entire continents and vast periods of time virtually unexplored. Future stable isotope studies will surely bridge these gaps, and in doing so will greatly increase our knowledge of early hominin diets. Yet, we should not be satisfied to merely work our way through previously neglected or unattainable material but should seek to push the limits of the technique itself. Improving our knowledge of the stable isotope compositions of modern plants and mammals, investigating how physiology affects diet-tissue spacing, and refining organic extraction techniques so that nitrogen isotopes can be analyzed for a wider variety of taxa, will not only improve our ability to reconstruct paleodiets, but will also enable us to address questions in ways that were previously unimaginable. Hopefully, such actualistic and experimental work will serve to hone this already exciting paleodietary tool.

Estimation of Basic Life History Data of Fossil Hominoids

Helmut Hemmer

Abstract

Relationships between the life cycle and body mass, brain mass and relative brain size of extant primates can be used to estimate life history parameters of extinct species. Methods to predict these key variables from available cranial and post-cranial materials of fossil hominoids, especially hominids, are compiled and evaluated. The use of different concepts of scaling relative brain size is discussed. Brain mass and constant of cephalization data were used as the source material for the estimation of the age at eruption of the first lower molar, the age at female sexual maturity, the age at first breeding, and the maximum life span. Such data support the interpretation of the Late Miocene *Sahelanthropus tchadensis* as a taxon possibly related to the hominid stem-species near the splitting of chimpanzee and hominid lines, confirm the fundamental nature of the australopithecines as progressive apes, not as humans, and support the view of a close relationship of the early Lower Pleistocene *Homo* paleopopulation of Dmanisi (Georgia) to the Late Pliocene but not to the Lower Pleistocene African *Homo* populations.

19.1 Introduction

Fossil bones are the material of classic osteological studies as a base of systematic and phylogenetic conclusions as well as the understanding of functional correlations of morphological structures. They also bear information that may be used for a two-step computing procedure to estimate fundamental life history, ecological and behavioral data that open a progressive level of insight into ecological relations.

Life history study is understood as an approach in evolutionary biology, identifying ontogenetic variables and then asking what impact those variables have on population size and composition. Relationships between the life cycle and anatomical variables, such as body size and brain size, are of particular
interest because they can be used to estimate life history parameters of extinct species (Hemmer 1974, 2003; Gingerich et al. 1982; DeRousseau 1990; Harvey 1990; Smith and Tompkins 1995), even if there are also life history components independent of brain and body size (Harvey and Read 1988).

The first step of such life history data calculation is the estimation of body mass as a key variable, supported by the estimation of brain mass, from available fossil remains. The second step then takes advantage of the first level results, to look for estimates of parameters of the individual’s life cycle, as the age at first reproduction or the maximum life span. How this subsequently affects higher levels of organization as, e.g., ecological aspects or population growth and evolution is an additional step of life history consideration (DeRousseau 1990; Hemmer 2003; Kappeler et al. 2003). This chapter focuses on the way to evaluate such basic information concealed in fossil bones, to look for hominoid, especially hominid, life history aspects. It does not deal with life history correlates as left by processes of growth, with “osteobiographic” techniques (Boyde 1990; Bromage 1990).

19.2 Life history correlations

Basic primate life history dimensions were found to correlate with body mass (Harvey and Clutton-Brock 1985; Harvey et al. 1987; Lee and Kappeler 2003) (Table 19.1), with absolute brain size (Sacher 1975; Harvey et al. 1987; Smith 1989; Smith et al. 1995; Deaner et al. 2003), and relative brain size.

Harvey and Clutton-Brock (1985: Tables 4, 5) or Harvey et al. (1987: Tables 16.3, 16.4); correlation coefficients based not on the species but on the subfamily level.
Brain size is more closely correlated with several life history variables, such as the age at sexual maturity or at first breeding, than is body size (Harvey et al. 1987). Unfortunately, data compilation in landmark publications (Harvey and Clutton-Brock 1985; Harvey et al. 1987) was confounded by conversion of cranial capacity with brain mass using a relationship $1 \text{ cm}^3 = 1 \text{ g}$ (Smith et al. 1995). Other studies were based on either cranial capacity or brain mass (Sacher 1975; Smith et al. 1995) (Table 19.2). The factor related to brain size was considered to be maturation rate as a whole rather than any one of its aspects (Smith 1989). There is an extremely high correlation of the age at eruption of the first lower molar, as a rather stable marker of growth with relatively low variance, and brain size ($r = 0.98$). When the effect of body mass is held constant in multiple regression, the partial correlation of $M_1$ eruption and adult brain size remains $r = 0.90$ (Smith 1989).

The use of relative brain size (constant of cephalization, see later) instead of absolute brain mass or cranial capacity in life history correlations (Hemmer 1974) eliminates the influence of body size and allows for some further improvement of the correlation coefficient with most variables. Allometric formulas that may be used as predictor equations for the estimation of life history data in fossil hominoid primates were calculated for the present contribution based on brain mass (brain and body mass data: Bauchot and Stephan 1969; life history data: Harvey and Clutton-Brock 1985) to avoid the former 1:1 confusion with cranial capacity data. The results for the relationship of body size, brain size, and coefficient of cephalization with the life history corner-stages age at sexual maturity, age at first reproduction, and maximum life span (data taken from the compilation of Harvey and Clutton-Brock 1985: Table 1), as well as age at first lower molar eruption and at completion of the dentition (data taken from Smith (1989), with modifications by Smith et al. (1995)), are listed in Tables 19.3 and 19.4 and illustrated in Figures 19.1 and 19.2).

19.3 Estimating body mass

Body size cannot be measured directly being an abstract concept not a concrete parameter. Size may variously be recorded, e.g., as head-body length or height at the withers in quadruped mammals or as stature in hominids, but for general use body mass undoubtedly is the most reliable measure and the size variable of choice (Gingerich et al. 1982; Jungers 1988; Ruff and Walker 1993; Aiello and Wood 1994; Hemmer 2004). Skeletal predictors may allow to estimate body mass on principle on the base of dentition (Table 19.5), skull (Table 19.6), and postcranial elements (Tables 19.7 and 19.8).

There exists no direct biomechanical relationship between tooth and cranial variables and body mass (Jungers 1988), but such dimensions nevertheless depend on a general factor of size. Dentition measurements may allow us to predict a genetically programmed frame of body size than the real size an individual reached during its ontogeny. Allometric relationships between tooth size and body mass have been used to reach the goal of body mass estimation in

extinct nongeneralized primates (Gingerich et al. 1982; Martin 1990; see discussion in Jungers 1990). This approach depends on what evolutionary grade of primate species is used to predict body mass (Conroy 1987), and would be a hazardous venture so far hominid evolution is concerned, in view of considerable changes of the relative size of the masticatory apparatus (Wolpoff 1973; Jungers 1988). Introduction of taxon-specific conversion factors (prediction by tooth size related to prediction by cranial or postcranial dimensions) may help to overcome that problem (as used in felid body mass prediction by Hemmer 2001, 2004). It must also always be taken in mind that dentition-based body mass estimates cannot present real individual life weights but merely provide some idea about a statistic mean to be awaited at a given linear predictor measure within a population in question.

Cranial dimensions should depend more closely than tooth dimensions on individual ontogenetic body size modeling. They allow us to predict some “normal mass” of an individual. Cranial dimensions prove in that generalized function in some cases to be nearly as good or even better mass predictors as are some of the best postcranial ones (Aiello and Wood 1994; Kappelman 1996). Nevertheless, cranial dimensions may also considerably mislead on the other hand. Comparing the average body mass estimated at the base of seven cranial predictors to the actual body mass of the respective species, the average prediction error (PE) was found to be ±32.3%, ranging from 0.5% to 79.3% (Martin 1990).

In limb bones, the genetic influences are supplemented by loading-related stimuli to a higher extant. They give evidence of an individual’s muscular strength and development (Lanyon 1990). Just here is a crucial point in hominoid evolution, where quadrupedal gait changed to bipedal gait or vice versa. Just skeletal structures that bear a direct functional relationship to body mass are to await to mislead in body mass estimation when the pattern of movement and the strains involved changed in that way. Predictor equations calculated for femoral diaphyseal diameters or circumferences, as well as for femoral articular dimensions (Jungers 1988, 1990; Kappelman 1996), also for cross-sectional geometrical data, such as cortical area or area moments of inertia (Ruff 1990), lose their utility when developed with quadrupedal hominoids but used for mass estimation in bipedal hominids [for convincing illustration of these issues see Figures 8.5, 8.7, and 8.8 in Ruff (1990) comparing femoral dimension allometric lines for

Figure 19.2
Bivariate log–log plots (lines: least-squares regressions) of age of eruption of the lower first molar (data by Smith 1989, with modifications by Smith et al. 1995) against body mass ($r = 0.979$), brain mass ($r = 0.985$), and constant of cephalization ($r = 0.981$) (data sources as for Figure 19.1)

Dimensions in mm (or mm²); numbers in square brackets refer to measurements numbers in Martin (Martin and Saller 1959). Body mass in g; equations in italics, body mass in kg.
Homo sapiens with those for pongids or nonhuman primates in general. Mass estimates based on femoral dimensions of a bipedal hominoid using predictor equations developed with a nonhuman hominoid sample should thus be awaited not to meet the real values (44% and 30% overestimates for human males and females with a catarrhine femoral head diameter regression: Kappelman 1996). Femur-based estimates gained with the use of equations calculated with hominoids including man should be shifted somewhat more in the direction of the true values but still differ from them. In the case of using pure Homo sapiens based predictor equations for body mass estimation in early hominids, caution needs to be exercised too, as all fossil hominids seem to have been characterized by considerable skeletal robusticity with thick long-bone cortices (Jungers 1988; McHenry 1992; Ruff and Walker 1993; Ruff et al. 1997).

If the fossil record of single Homo skeletons is complete enough to know body height (stature) and width (bi-iliac breadth), relatively accurate body mass estimations will be possible based on these dimensions (Ruff and Walker 1993; Ruff et al. 1997) (Table 19.8), provided that there are no basic differences in body proportions.

A crude approach to body mass of fossil hominoids other than simple comparisons among hominoid skeletons (for compilation of earlier trials of that type see Suzman 1980) may be done on the basis of close correlations of some cranial and postcranial dimensions with partial skeletal mass to represent body size (Steudel 1980). This procedure allows to compare fossils with the body mass of large, slightly larger than average, average, slightly smaller than average, or small male or female actual ape species. Approaches to body mass estimation in early hominids by a prediction of body height on the basis of postcranial elements and the subsequent use of a body height to body weight ratio (Wolpoff 1973) must meet the requirements of the same stature class, for which the ratio was calculated, and of the same limb to body proportions. Finally, another

BM, body mass (kg); ST, stature (cm); BI, bi-iliac breadth (cm): before applying these formulas, skeletal bi-iliac breadth is converted to living bi-iliac breadth using the equation living BI = 1.17 skeletal BI – 3 (Ruff et al. 1997).
simplified attempt to estimate body mass of early hominids exclusively at the base of the cube of limb bone length or the square of diameter percentage deviations from a *Homo sapiens* standard skeleton (Krantz 1977) may not result in much more trustful body mass estimates than heavier, much heavier, or lighter, much lighter than the standard, as such a procedure neglects size-dependent allometric shifts and evolutionary changes in body proportions.

It should always be kept in mind that body mass estimates resulting from either cranial or postcranial variables are subject to considerable error (Jungers 1990; Martin 1990; Ruff and Walker 1993; Aiello and Wood 1994; Kappelman 1996). Given this fact (Table 19.5) and the use of equations based on highly correlating samples ($r \geq 0.95$; the correlation coefficient depends on the overall size variability and allows for higher values in all primate samples than in taxon specific samples, but the latter otherwise may have a higher misleading potential for predicting equations used for extinct species), different available line-fitting techniques to create predicting equations (least-squares regression, reduced major axis, major axis) and the partial availability of correction factors to compensate for bias, introduced when a body mass estimate derived in logarithmic units is detransformed back to arithmetic units (Smith 1993), as well as many other issues around estimation of body mass in paleontology (Smith 2002), may not really merit that high attention for practical use as sometimes postulated (Gingerich et al. 1982; McHenry 1992; Hartwig-Scherer 1993; Aiello and Wood 1994; Kappelman 1996). Individual body mass estimates of fossil specimens of course may be calculated that are mathematically quite correct, even to the nearest 100 g, for further statistical use; but nevertheless it is biologically wise to list them not in that accurate form but as roughly rounded values. To give a comparable example, rounding to the nearest kilogram was proposed for body mass prediction in fossil cats only for specimens weighing less than 20 kg, to the nearest 5 kg for the range between 20 and 50 kg, to the nearest 10 kg for specimens weighing more than 50 kg (Hemmer 2004).

### 19.4 Estimating brain mass

Cranial capacities measured in cm$^3$ are not the same as brain masses measured in g. In primates, the general relationship will be cranial capacity $>$ brain mass $>$ brain volume (Smith et al. 1995). Unfortunately, this is not always done in comparative publications [e.g., cranial capacities labeled brain mass in Table 1 of Harvey and Clutton-Brock (1985), identical with Table 15-1 of Harvey et al. (1987); see Smith et al. 1995]. There is also no stable relationship between brain mass and cranial capacity [e.g., 1/1.05 as used for humans by different
authors (Smith et al. 1995) or 1/1.14, as used by Hartwig-Scherer (1993), following Count (1947)] over the whole range of brain size variability. The repeatedly found allometric exponent of 1.02 (Martin 1990, for primates; Röhrs and Ebinger 2001, for mammals other than primates) does not mean an isometric relationship between the two variables at correlation coefficients as high as 0.995–0.997 (Table 19.9a). Therefore, all comparative work using brain size should either center on cranial capacities or brain masses. Calculations of relative brain size (cephalization, encephalization quotient) based on body mass clearly should proceed with brain mass. Unfortunately, the available predictive equations for primates or mammals in general give quite differing brain mass values (Table 19.9b). The primate cranial capacity brain mass conversion formula (Martin 1990) is retained here, since it neither produces clearly excessive values in the upper

Homo sapiens range in view of such conversion data as presented by earlier authors [compilation in Martin and Saller (1959)], nor nonsense values in the lower range, whereby brain volumes would become just larger than cranial capacities (as produced with the use of the formula of Ruff et al. 1997).

It should be noted that there are some pitfalls in the determination of the cranial capacity as basis for brain mass estimation. The usual method of packing the cranial cavity with small rounded particles as lead shot, mustard seed or millet grain, and other comparable materials is limited by the need to condense the fill both in the skull and in the measuring cylinder in the same way. The method closing the foramina before packing the cranial cavity may also influence the result. A good standardized practice is needed to achieve a tolerable accuracy with this volumetric approach, and it may be combined with a weighing procedure (Smith et al. 1995). Measurements obtained by the packing method may surpass the volume of artificial endocasts (Martin 1990, Table 8.5: 10–11% in the Eocene lemuroid primate Adapis parisiensis). Estimation of endocranial volume by double graphic integration derived from X-ray pictures may result in substantially diverging values (Martin 1990, Table 8.5: 10–12% less than the artificial endocast in Adapis parisiensis). An assessment of cranial capacity in fossil primates also may be done by the use of linear cranial dimensions (Martin 1990) (Table 19.10).

The formulas are based on the major axis, the cranial capacities were determined by packing the cranial cavity with sintered glass particles.

### 19.5 Calculating relative brain size

There are four main concepts of scaling relative brain size in primates (McHenry 1976). The constant of cephalization (CC) (Hemmer 1971) was developed on the base of a common mammalian intraspecific allometric exponent around 0.23
[\text{BrM} = \text{CC} \times \text{BM}^{0.23}; \text{BrM} = \text{brain mass (g)}, \text{BM} = \text{body mass (g)}]. \text{The index of progression (IP) (Bauchot and Stephan 1966, 1969) gives the ratio of actual brain mass to brain mass predicted on the basis of an interspecific basal insectivore allometric equation with an exponent of 0.63. [The index of cranial capacity (ICC) as introduced by Martin (1990) follows just the same lines as the index of progression.]} \text{The encephalization quotient (EQ) (Jerison 1973) is also the ratio of actual to predicted brain mass, the latter based on an interspecific mammalian allometry (predicted brain mass} = 0.12 \text{BM}^{2/3}). \text{The extra neurons count (Nc) (Jerison 1973) “is a numerical measure of progressiveness in brain development beyond the level required by increasing body size” (Jerison 1973). The results of the CC and Nc methods perfectly correlate on the one hand as do the results of the IP and EQ methods on the other (Figure 19.3). This reduces the issues on principle to the choice of either the intraspecific (CC and Nc methods) or the interspecific (IP and EQ) type of brain to body mass allometries.}

\text{EQ has been widely used in the last three decades by the overwhelming majority of authors (Hartwig-Scherer 1993; Kappelman 1996; Ruff et al. 1997; McHenry and Coffing 2000). The results of EQ calculations vary depending on which of the different equations is selected (Kappelman 1996) [allometric exponents varying from 0.60 (Old World simian EQ: Martin 1990) or 0.67 (Jerison 1973) close to 0.75 (0.74–0.76) (Martin 1990; Hartwig-Scherer 1993; Ruff et al. 1997; McHenry and Coffing 2000)]. Nevertheless, some writers have begun to feel uncomfortable about the EQ method (McHenry 1988; Kappelman 1996; Arsuaga et al. 1999; Rightmire 2004). A negative allometric relationship between body size and EQ was raised, but the reasons were assumed to be unclear (Kappelman 1996). EQ being a function of body mass predicted for individuals using an interspecific equation, the comparison of EQ values determined for fossils was considered to be misleading (Rightmire 2004). Similarly, the EQ was not felt to be meaningful when closely related species with widely differing body mass are compared (Arsuaga et al. 1999). Curious EQ results like a position of \textit{Miopithecus talapoin} above all nonhuman hominoids, the gorilla ranging below all cercopithecines (Hemmer 1971: Table 2), or \textit{Cebus albifrons} lying between \textit{Homo erectus} and \textit{Homo sapiens} (Hartwig-Scherer 1993: Fig. 6) also indicate that this procedure may be seriously biologically inadequate. All such problems disappear when the CC intraspecific approach is followed instead of the EQ interspecific method (Hemmer 1971). As a by-effect of the low-intraspecific allometric exponent, the influence of differences in body mass predictions on EQ calculations (Conroy 1987) is less profound with the CC method.}
Bivariate log–log plots (lines: least-squares regressions) to demonstrate the mutual relationship of the main methods to scale relative brain size (data from McHenry 1976: Table 2; hominoid primates). (a) Extra neurons count (Nc) (Jerison 1973) against constant of cephalization (CC) (Hemmer 1971), $r = 0.997$. (b) Encephalization quotient (EQ) (Jerison 1973) against constant of cephalization (CC), $r = 0.971$. (c) Encephalization quotient (EQ) against index of progression (IP) (Bauchot and Stephan 1966), $r = 0.998$. 

\[ N_c \sim 10^r \]

\[ EQ \sim 10^r \]
19.6 Life history data estimations in fossil hominids

The final approach to life history data estimation in fossil hominoids, especially in fossil hominids, is a story of reliability of the prediction equations to be used. There is a wide variability in the results of body mass estimation obtained on the basis of different species samples used to create the equations, on the basis of different dimensions, and using different line-fitting techniques (Table 19.11). The availability of several parts of a single skeleton, as e.g., in the female *Australopithecus afarensis* AL 288-1 specimen, allows for many independent estimates, that group together centrally to resemble a normal distribution, to give a clear and conclusive view of the most probable body mass of that individual, and to allow easy recognition of outsider values (Figure 19.4). In the AL 288-1 case, the peak of the density curve (made up of 54 estimates) is found near 29 kg, the mean and the median range near 30 kg, allowing for a consistent estimation of body mass roughly around 30 kg, as also found in earlier studies (Jungers 1988, 1990; McHenry 1992). The existence of such a key specimen also allows us to judge empirically which predictors may be more useful and which should be excluded from the estimation process for a taxon for which neither humans nor African apes are completely adequate models (Hartwig-Scherer 1993). For AL 288-1, dimensions of the humerus and radius heads and the elbow joint (McHenry 1992) produce clearly estimates that are too small based on general hominoid allometries as does the size of the sacral body (McHenry 1992). On the other hand, very large estimates result from the circumference of the humerus based on *Homo sapiens* allometry and from the circumference of the tibia based on an African ape allometry (Hartwig-Scherer 1993), while the dentition provides an outsider value (Jungers 1988).

The availability of well-founded body mass estimates based on postcranial predictors allows us to determine which cranial predictors compare in reliability with them for *Australopithecus* and early *Homo* as well. Orbital height was extracted as the cranial variable which produces body mass estimates that are most in line with postcranially generated estimates (Aiello and Wood 1994). This may be supplemented by estimates based on a computer digitizing measurement of the orbital area (Kappelman 1996).

Published body mass estimates based on these cranial dimensions were used together with most relevant postcranially predicted data to extract rounded mean body mass for *Australopithecus* and *Homo* paleopopulations and to calculate in each case the CC with rounded mean brain mass converted from mean cranial capacity (Tables 19.12 and 19.13). These brain mass and CC data were then used as the source material for the estimation of life history traits. The evaluation of the reliability of the life history trait predictor equations (Tables 19.3 and

ecological factors. Any prediction for extinct populations will be subject to this variability too.

Nevertheless, the results then obtained confirm, correct, and supplement earlier [Hemmer (1974) on the age at sexual maturity, at first breeding, and at teeth eruption in *Australopithecus*] and later calculations [Smith and Tompkins (1995) on first permanent molar eruption]. At the same time, they are supported by results of osteobiographic techniques. *Australopithecus* (*afarensis, africanus, robustus*) and early *Homo* specimens, aged at something like 3–3.5 years on the basis of incisor crowns with little or no root development, had first permanent molars coming into occlusion (Bromage 1990) just as predicted with first lower molar eruption at around 3 years (Table 19.14). The estimation of life history data confirms the fundamental nature of the australopithecines as progressive apes, not as humans, the early *Australopithecus afraransis* ranging within the modern African ape life history dimensions.

Some important new fossil taxa discovered in the last years are included in the selected samples of life history data presentation (Table 19.14). The interpretation of the Late Miocene *Sahelanthropus tchadensis* (Brunet et al. 2002), as a taxon possibly related to the hominid stem species near the splitting of chimpanzee and hominid lines (Brunet et al. 2002; Wood 2002), may be supported by the estimation of life history dimensions that indicate an earlier evolutionary stage than all *Australopithecus* and *Homo* paleopopulations at the one hand and than the chimpanzee on the other. The Lower Pleistocene (Upper Villafranchian) *Homo* paleopopulation of Dmanisi (Georgia) (*Homo georgicus* Gabounia et al., 2002) has been interpreted as more closely related to the Late Pliocene *habilis and rudolfensis* than to the Lower Pleistocene *ergaster and erectus* (Gabunia et al. 2000; Gabounia et al. 2002; Vekua et al. 2002). The life history estimates clearly support this view. The so-called *Homo floresiensis* (Brown et al. 2004) is not integrated here, as this specimen obviously neither represents a new species nor an enigmatic branch of hominid evolution, but is just a classic microcephalic *Homo sapiens* individual, sharing the characteristic syndrome of pygmy size, very small (chimpanzee sized) brain, and considerably aberrant skull.

Estimation of basic life history data of fossil hominoids

Abstract

The study of population genetics can contribute to paleoanthropological research in three ways. First, the analysis of genetic variation in living human populations can provide information about past events, including the time and place of recent common ancestors, which when considered over many loci can give us clues regarding patterns of human evolution. Recent work in this area supports a view of several dispersions out of Africa, with the later two corresponding roughly to the appearance of the morphospecies *Homo heidelbergensis* and modern *H. sapiens*, but in both cases showing evidence of dispersions with admixture, rather than dispersions with replacement. Second, studies of ancient DNA, such as those conducted to date on Neandertal fossils, can potentially give us insight into ancient genetic variation and relationships among populations or taxa. Evidence to date suggests that Neandertals may have contributed little in overall ancestry to living humans, but it is still not clear whether they contributed nothing genetically. Third, mathematical models and simulations based on population genetic theory can help us formulate and refine hypotheses regarding human evolution by providing an idea of what patterns should be expected in the fossil record under alternative evolutionary scenarios.

20.1 Introduction

The use of genetic data and genetic inferences in paleoanthropological research has become increasingly accepted in recent years. This was not always the case. Sarich and Wilson (1967) proposed a method of “molecular dating” that when applied to data from extant hominoid species led to the then-radical conclusion that the African ape and human lineages had diverged only 4–5 Ma, rather than the more accepted 15+ million-year date based on many interpretations of the fossil record available at that time. Over time, the late-divergence hypothesis became accepted by the majority of the paleoanthropological community because of both additional fossil evidence as well as a growing acceptance of molecular
methods (Lewin 1987; Tattersall 1995). Since the mid-1980s, genetic data and inferences have become part of the effort to unravel the origins of modern humans. Over the years, numerous books and articles have reviewed the subject of genetics and modern human origins. My purpose here is not to provide a detailed overview of previous studies and reviews, but rather to highlight the major uses and possible future directions of population genetic data and models in the search for modern human origins.

20.2 Models of modern human origins

The modern human origins debate is concerned with the evolutionary relationships between “archaic” and “modern” humans over the past 200,000 years. Although it is clear on a very general level that archaic humans gave rise to anatomically modern humans, the specifics of this transition make up the modern human origins debate. A certain amount of the debate over modern human origins may lie in differing interpretations of the evolutionary models that have been proposed to explain this transition. Although it is quite typical to see this debate phrased in terms of a conflict between a “recent African origin” and “multiregional evolution,” in reality the situation has been more complex, in part due to the fact that there are several variants of each model, sometimes overlapping in terms of underlying predictions. Elsewhere (Relethford 2001c), I attempted to condense much of this debate by focusing on two basic questions: (1) what was the mode of this transition? and (2) what is the location and timing of this transition? The joint answer to both of these questions determines the specific nature and predictions of various modern human origin models.

The mode of transition refers to whether modern humans arose through speciation and replacement of archaics outside the region of transition or through evolution within a species across most or all of the Old World. In others words, the debate here is about cladogenesis versus anagenesis. Although this distinction is clear in terms of the contrast between the recent African origin and multiregional evolution models, the question of the location and timing of the transition is fuzzier. Here, there are two different views: one arguing that the transition took place in a single area (Africa) at a specific time, and the other arguing that there was no single time or place associated with the origin of modern humans. Rather, the transition from archaics to moderns occurred piecemeal across the Old World, with such changes coalescing throughout the entire species due to gene flow. Although much of the literature supporting multiregional evolution takes this latter view, it is important to realize that there are advocates of multiregional evolution (as a general process) that argue
for a single and recent African origin of modern humans (Wolpoff et al. 1994; Relethford 2001c).

### 20.2.1 Models

I have argued elsewhere that consideration of the issues of mode and timing/location leads to three general classes of models (Relethford 2001c). The first is the African Replacement Model, which argues that modern humans arose through cladogenesis as a new species (*Homo sapiens*) in Africa roughly 150 to 200 ka or so. Over time, this new species expanded out of Africa and eventually replaced all preexisting archaic populations outside of Africa. Under this model, various non-African archaics, such as the Neandertals of Europe, became extinct and did not contribute genetically to living humans because they were, by definition, a separate species. This model links the mode of cladogenesis with the idea of a single origin point.

The second model is the Regional Coalescence Model. This model is usually associated with one commonly used definition of multiregional evolution. Here, the transition from archaics to moderns took place within a single evolving lineage (anagenesis) and there was no single time or place associated with this transition. Proponents of this view argue that the boundary between “archaic” and “modern” implies a lack of a clear point of transition. Instead, changes occurred over time in different geographic regions, which ultimately were shared across the range of the species through gene flow (although it is not necessary under this model that *all* populations ultimately contributed ancestry to modern humans).

The third model is the Primary African Origin Model. This model shares the idea of a species-wide transition with the Regional Coalescence Model and the idea of a single point of origin (Africa) with the African Replacement Model. Here, the transition from archaic to modern humans took place in Africa roughly 150 to 200 ka, followed by an expansion of some populations out of Africa by 100 ka. However, unlike the African Replacement Model, this model allows admixture between expanding modern populations and the preexisting archaic populations outside of Africa. Different variants of this model emphasize different forms of this admixture, including isolation by distance effects, long-range migration, demic diffusion, and various combinations of all of the above. The Primary African Origin Model shares not only an explanation of mode of evolution with the Regional Coalescence Model but also the idea of a specific recent African origin with the African Replacement Model. Because the Primary African Origin Model invokes genetic ancestry from more than one region, it is by broad
definition a multiregional model. However, because of its proposed single and recent origin of anatomical modernity, it is also by broad definition a recent African origin model. Some examples of models which I feel fall into the category of “Primary African Origin” models are Bräuer’s (1992) “Afro-European hybridization” model, Smith et al.’s (1989) “assimilation” model, Relethford’s (2001c) “mostly out of Africa” model, and Eswaran’s (2002) “diffusion wave” model.

20.2.2 Fossil record

Before considering the relevance of genetics to testing of these models, it is necessary to briefly consider the current status of the fossil record on the timing and appearance of anatomically modern humans. Although not everyone agrees, there appears to be growing consensus that the earliest evidence of modern human anatomy is in Africa dating back more than 100 ka, perhaps as far back as 195 ka at Omo (McDougall et al. 2005). Recent discoveries from the Middle Awash show evidence of a transition between archaic and modern morphology almost 160 ka (White et al. 2003). If the finding of an earlier presence of anatomically modern humans in Africa persists, then it seems likely that the Regional Coalescence Model of modern human origins will be rejected. The fossil evidence, along with genetic evidence pointing to a central importance of Africa in modern human evolution, supports a recent African origin, although this by no means automatically supports a speciation and subsequent replacement. Although this point gets glossed over in many treatments of the modern human origins debate, a recent African origin is not incompatible with some versions of multiregional evolution, specifically the Primary African Origin model (Relethford 2001c). In terms of the two debate issues discussed earlier (mode of transition and timing/location of transition), the latter issue seems settled for many anthropologists—modern humans began, as an anatomical form, in Africa about 150 to 200 ka. What remains contentious is the genetic interaction, if any, between modern humans dispersing out of Africa and the preexisting archaic humans outside of Africa. Thus, the debate at present is primarily between replacement and admixture. A further complication is the distinct possibility that both replacement and admixture occurred, each in different areas outside of Africa.

20.2.3 Population genetics and modern human origins

In broad terms, the study of population genetics can be applied to the study of modern human origins in three ways: (1) analysis of patterns of genetic variation in living human populations, (2) analysis of patterns of ancient genetic
variation, specifically ancient mitochondrial DNA (mtDNA), and (3) application of models of population genetics to the fossil record. Of these, the first two are widely known and discussed, whereas the important contributions of population genetics models for interpreting the fossil record have received less attention, but it is likely to be an important concern of future research in modern human origins.

20.3 Patterns of genetic variation in living human populations

Anthropologists and human biologists have been collecting information on patterns of biological variation within and between living human populations for several centuries, starting with anthropometrics and other physical measures, followed by blood types in the early twentieth century, and blood proteins and enzymes in the latter half of the twentieth century. Over the past two decades, newer genetic markers brought about through an ongoing revolution in molecular genetics have allowed us even closer glimpses and genotypes and underlying genetic code. This massive and everincreasing store of data on contemporary human genetic variation has definite implications for paleoanthropological research. The rationale here is that whatever happened in the past, these events have left a genetic signature on patterns of contemporary genetic variation. Our current patterns of genetic diversity are in essence “reflections of our past” (Relethford 2001c, 2003). The trick is being able to discern ancient population dynamics from current patterns of genetic variation in such a way that specific hypotheses can be tested. In some cases, the immediately obvious inferences made from contemporary genetic variation have turned out to be more complex than once thought, or often reflecting several possible past histories.

20.3.1 Gene trees

The molecular revolution has allowed detailed glimpses into the mutational history of specific genes and DNA sequences. Reconstruction of gene genealogies (gene trees) allows us the ability to identify the most recent common ancestor (MRCA) of any set of sequences from contemporary populations. If our sampling is geographically diverse, identification of the most recent common ancestor provides information on all of humanity, which in turn can have implications for modern human origins. Such analyses can then tell us something about the time back to the most recent common ancestor (TMRCA) and the place of the most recent common ancestor (PMRCA) (Takahata et al. 2001).
The best known example of this type of work resulted from early analyses of mtDNA variation in living humans. Mitochondrial DNA is a useful trait for genealogical analysis because it is inherited strictly through the maternal line and does not recombine (Stoneking 1993). The relatively high mutation rate of mtDNA means it is particularly useful for more “recent” evolutionary events. The application of mtDNA variation to the debate over modern human origins came with the study of Cann et al. (1987) which showed that the most recent common mtDNA ancestor lived in Africa roughly 200 ka. These findings were later verified by other studies (Vigilant et al. 1991; Penny et al. 1995). The significance of these findings lay in the fact that the most recent common ancestor lived well after the initial dispersion of Homo out of Africa. The date of 200 ka (even given a wide confidence interval) led many to reject any sort of multiregional interpretation of modern human origins on the grounds that multiregional evolution, with its emphasis on a single evolving lineage of Homo, required common ancestry back to 2 Ma. One problem, later described in many reviews (Relethford 2001c; Klein and Takahata 2002), is that the mtDNA gene tree described the history of that particular trait alone, and that the history of a gene or DNA sequence may not necessarily reflect the history of a population. It has since been realized that a more accurate reconstruction of modern human origins requires synthesis of a number of different gene trees, including those available from mtDNA, Y-chromosome DNA, and segments of nuclear DNA that show little if any recombination.

Several studies have examined patterns of common ancestry based on multiple gene trees. Takahata et al. (2001) examined data from autosomal, X-chromosome, Y-chromosome, and mitochondrial sequences. Nine out of 10 of these sequences showed the most recent common ancestor in Africa, and the 10th sequence was Asian in origin. They argued that the results favored a single African origin but did not rule out some non-African ancestry under the condition that the founding population in Africa was much larger than outside of Africa. This conclusion is interesting because other genetic data support a larger long-term African population size (Relethford and Harpending 1994; Relethford and Jorde 1999). The dominant genetic signature from Africa, combined with evidence of some non-African ancestry, is best explained by a primary African origin model.

Another multivariate approach to gene tree analysis has been undertaken by Templeton (2002, 2004), who used a complex method known as nested clade phylogeographic analysis which can identify both unique historical events, such as population dispersions, and ongoing recurrent events, such as gene flow. This method was applied to data on mtDNA, Y-chromosome DNA, X-chromosome DNA, and autosomal DNA haplotypes. The comparison of results across these difference sequences showed that there has been more than one dispersal out of
Africa (Templeton 2004). The mtDNA and Y-chromosome DNA sequences indicated a fairly recent dispersion with an estimated age of 80–150 ka. However, other sequences showed another earlier dispersal out of Africa occurred roughly 420–840 ka. Combined with the fossil evidence for a dispersal of \textit{Homo} out of Africa roughly 1.8 Ma, Templeton (2002) therefore argued that there have been three distinct African dispersals. Although the confidence intervals are broad, the latter two African dispersals coincide roughly with morphological changes in \textit{Homo}: the increase in brain size roughly 700 ka (Relethford 2001c) and the emergence of anatomically modern human crania out of Africa 100 ka.

Multiple dispersions out of Africa can fit either a replacement model or an admixture model. In the case of the replacement model, each dispersal might correlate with the rise of a new species in Africa: \textit{H. erectus} followed by \textit{H. heidelbergensis} followed by \textit{H. sapiens}. One could argue that in each case a new species arose in Africa and then dispersed across the Old World to replace the preexisting species. In the case of an admixture model, much the same thing could have occurred, but with new morphological changes spreading through gene flow, rather than replacement, outside of Africa.

Templeton’s nested clade phylogeographic analyses provide some resolution to the replacement/admixture debate by noting different predicted patterns of haplotype variation under conditions of range expansion and those of recurrent gene flow and isolation by distance. Templeton (2002) concluded that there is ample evidence of recurrent gene flow between geographic regions throughout the past 2 Myr, suggesting that the two dispersals out of Africa following the initial dispersion of \textit{H. erectus} resulted in interbreeding rather than replacement. If true, then the evolution of the genus \textit{Homo} has been characterized by a series of expansions out of Africa, with each subsequent expansion occurring on top of previous ones, in addition to some level of interregional gene flow over time. The appearance of new morphological variants, such as archaic and modern humans, would thus represent an evolutionary shift within a single lineage rather than a series of speciation events. It is less clear, however, how to distinguish these possible scenarios in the fossil record. Depending on the relative speed of dispersal and replacement versus admixture, the two models might produce essentially the same pattern of morphological change within \textit{Homo}—early humans (\textit{H. erectus}) followed by archaic humans followed by modern humans.

### 20.3.2 Genetic diversity

Another significant finding of population genetics research on living populations has been the discovery that sub-Saharan African populations show greater
diversity than do populations in other geographic regions. This pattern of higher levels of variation has been found in mtDNA (Cann et al. 1987; Vigilant et al. 1991), microsatellite DNA markers (Jorde et al. 1995), Alu insertion markers (Watkins et al. 2001), craniometrics (Relethford and Harpending 1994), and skin color (Relethford 2000).

The evolutionary significance of higher sub-Saharan African diversity, and its implications for the question of modern human origins, has been debated. One explanation is that diversity is a reflection of the age of a population; the longer a population has been around, the more mutations have accumulated, and hence the older it is. Under this model, as a daughter population splits off from a parental population to form a new founding group, the small size of the founding group results in genetic drift such that the level of diversity is “reset” and future mutations then accumulate since the time of founding. Given the assumption of diversity correlating with age, it has been argued that higher levels of sub-Saharan African diversity thereby support a replacement model. If modern humans arose first in Africa, and non-African populations formed as founder groups later in time, then we would expect to see exactly the same pattern as we find today—higher levels of genetic diversity in sub-Saharan Africa. Although this finding does at first glance support an African origin of modern humans, it does not necessarily rule out admixture outside of Africa. In addition, we also need to be cautious when making inferences about age from diversity because the underlying assumptions about magnitude and duration of a bottleneck effect may be too unrealistic to apply to the evolution of modern humanity (Rogers and Jorde 1995; Relethford 2001c).

Furthermore, there are other factors that influence diversity that are more realistic, primarily gene flow and population size. As shown in analyses of craniometric data (Relethford and Harpending 1994) and microsatellite DNA markers (Relethford and Jorde 1999), higher levels of phenotypic/genetic diversity in sub-Saharan Africa are likely due to larger population size in Africa. Because of the relationship between population size and genetic drift, smaller populations will experience more genetic drift and hence have lower levels of diversity. A larger African population size is consistent with likely prehistoric population density, ecology, and overall land mass (Hassan 1981; Thorne et al. 1993).

It is important to note, however, that a larger African population size is possible under virtually any model of modern human origins, and the fact that genetic evidence points to this finding does not verify or rule out either replacement or admixture. On the other hand, it does point again to the importance of Africa in the genetic structure of living humans. A larger long-term African
population size means that, evolutionarily, the majority of our ancestors in recent evolutionary history are likely to have lived in Africa. However, it is not clear whether all of our recent ancestors are African, as required by a speciation and replacement model. As I suggest elsewhere (Relethford 2003), the question boils down to where our ancestors lived some 150 to 200 ka. Under a replacement model, all of them were African, whereas all other models suggest that some of them were African. The higher levels of African genetic diversity, likely reflecting larger African population size, agree with other genetic and fossil evidence of an African origin for anatomically modern humans, but it does not distinguish between replacement and admixture.

Similarly, geographic patterns in genetic diversity can be explained under either a replacement or admixture model. Some genetic studies have found a pattern of diversity where non-African diversity is a subset of African diversity in terms of haplotypes (Tishkoff et al. 1996; Watkins et al. 2001). Although this pattern fits nicely with an African origin and subsequent dispersion and replacement, it can also be accommodated with an admixture model with larger African population size. In simplest terms, lower non-African population sizes throughout much of human evolution would have caused greater genetic drift outside of Africa, which in turn could lead to non-African diversity reflecting a subset of African diversity due to loss of haplotypes under genetic drift. Again, this could have happened under either a replacement or admixture scenario depending on particular parameter values.

### 20.3.3 Population genetics and coevolution of host and parasite

A new type of genetic analysis that can provide insight into human evolution is the study of the genetic history of human parasites. One recent example is the study of Reed et al. (2004) on the evolutionary history of the modern human head louse, *Pediculus humanus*. This species has two lineages, one globally distributed and the other found only in the New World. Genetic analysis suggests that these two lineages separated roughly 1.2 Ma. The presence of both louse lineages in living humans is best explained by a host switch later in time after this divergence, which in turn suggests close physical contact between *H. erectus* or archaic humans and modern humans. These results do not resolve the debate over replacement versus admixture because the physical contact between previously divergent human populations might have been nonsexual, or if sexual it might not necessarily have resulted in fertile offspring.
20.3.4 What does the genetic evidence tell us?

Patterns of genetic variation within and between living populations can have a number of different causes that do not distinguish clearly between certain models of modern human origins. This problem of indeterminacy also applies to other observations from genetic data, such as patterns of genetic distance between populations and observations of prehistoric population expansions (Relethford 2001c). Taken as a whole, the genetic evidence certainly points to sub-Saharan Africa as having had a major effect on shaping contemporary patterns of human genetic diversity probably due to an earlier appearance of anatomically modern humans (as seen in the fossil record) combined with a larger African population size. Again, the difficulty is resolving whether this African origin was followed by replacement or admixture. Many classic models of genetic analysis, many of which are based on an a priori assumption of no gene flow, are unable to resolve this problem, and it will require the development of new methods. To date, the most promising is Templeton’s nested clade phylogeographic analysis method. Given the haplotype data collected to date, his analyses suggest that the most parsimonious model of modern human origins is a set of African dispersals overlain on top of each other, along with some continuing recurrent gene flow. If these results hold up as more genetic data accumulate, then the data are best interpreted as showing admixture outside of Africa, although it remains to be seen how much admixture occurred in any given geographic region.

20.4 Ancient DNA

Another genetic approach to human evolution is the relatively new analysis of ancient DNA sequences. I recall a conversation years ago in graduate school where someone made the statement that many debates in human evolution could be solved if only we had genetic data from the past. Such statements seemed harmless enough at the time, given that the idea of extracting genetic data from fossil remains was essentially science fiction at the time, and we expected that such accomplishments were impossible. We were wrong, but on two counts. First, it is possible under appropriate conditions to sequence ancient DNA. Second, the data are not always quite as clear as we imagined they would be. Although some scientists have taken the results from ancient DNA analysis as unambiguous evidence pertaining to modern human origins, others are still skeptical about exactly what these data show us.
20.4.1 Neandertal DNA

The revolution in the use of ancient DNA analysis in the modern human origins debate came with the sequencing of small sections of mtDNA from the Feldhofer Neandertal (Krings et al. 1997, 1999). In the original analysis, Krings et al. (1997) compared a 378-bp Neandertal sequence with mtDNA sequences from living humans. The results were very clear in showing that the Neandertal mtDNA sequence was quite a bit different; the average difference between Feldhofer and living humans is 27 base substitutions, over three times the average difference between random pairs of living humans. Taking this difference as supporting the idea that Neandertals were a separate species, they further derived an estimate of between 550 and 690 ka as the time when the Neandertals and our own ancestors diverged. Since the initial sequencing of the Feldhofer specimen, additional Neandertal mtDNA sequences of varying length have been extracted from several specimens at different sites (Krings et al. 2000; Ovchinnikov et al. 2000; Schmitz et al. 2002; Serre et al. 2004). Collectively, these sequences cluster together and are quite different from those of living humans (although see Gutierrez et al. 2002 for an alternative analysis).

To date, several findings have generally, although not universally, been regarded as supporting replacement of the Neandertals by anatomically modern humans. One such finding has been the overall magnitude of the difference between the Neandertal DNA sequences and those from living humans. However, the meaning of this difference is less clear, as studies on comparable mtDNA sequences in living chimpanzees show that the difference between two out of three comparisons of chimpanzee subspecies is less than that between Neandertals and living humans (Krings et al. 1999). Based on this finding alone, one could argue that Neandertals were at most a different subspecies from us and not a different species (Relethford 2001c).

Another argument that has been made in favor of the replacement model is the fact that Neandertal mtDNA sequences (from Europe) are no more similar to living Europeans than to living humans from other regions (Krings et al. 1997). That is, Neandertal DNA is essentially equidistant from living humans in all geographic regions, a pattern that is consistent with the view that Neandertals diverged before the geographic dispersal of modern humans, and therefore were a separate species. Elsewhere I have questioned this conclusion, and showed that under conditions of interregional gene flow and given sufficient time, the same equidistant pattern of similarity could result without replacement (Relethford 2001a). Of course, this finding does not mean that the replacement hypothesis
is wrong, but instead that the equidistant pattern of mtDNA similarity does not necessarily reject alternatives.

**20.4.2 Early modern human DNA**

The strongest evidence supporting replacement and the extinction of the Neandertal gene pool is the lack of Neandertal sequences in any of the thousands of mtDNA sequences obtained to date from living humans. Although one explanation for the lack of Neandertal-like sequences in living humans is replacement, another possibility is that Neandertals constitute part of the ancestry of living humans but mtDNA lineages have been lost over time because of genetic drift. Adcock et al. (2001b) obtained mtDNA sequences from a number of prehistoric Australian modern human fossils including the Lake Mungo 3 (LM3) fossil, which might date back over 60,000 years. The mtDNA sequence for LM3 was different from both Neandertals and living humans. One explanation is that the mtDNA lineage in LM3, a fossil that is clearly anatomically human, has been lost due to drift over thousands of years. Although this find does not bear directly on the Neandertal issue, the fact that drift could cause the loss of an mtDNA lineage in one part of the world (Australia) means that it is possible the same thing happened in Europe (Relethford 2001b). Again, however, the observation that something could have happened does not mean that it did happen (see also Cooper et al. 2001 and Adcock et al. 2001a for debate over possible contamination and analysis).

One potential solution to the problem of drift over time is the comparison of Neandertal DNA sequences with those obtained from early modern European fossils rather than with living Europeans. Caramelli et al. (2003) extracted mtDNA sequences from two anatomically modern human fossils from Italy dating to 24 ka. These sequences were quite similar to those from living humans but different from Neandertal sequences. One interpretation of these results is that there has been little change in mtDNA sequences in the modern human lineage over time, and therefore that Neandertals, with much greater sequence differences, were a separate species. One problem with this interpretation is that contamination from living humans could lead to the same result. In an attempt to get around the problem of potential contamination, Serre et al. (2004) have suggested that it is more appropriate to determine if Neandertal-like sequences rather than present-day sequences were present in early modern human fossils. Using Neandertal DNA primers, they showed that there were no Neandertal-like sequences present in five early modern human fossils. Based on these results, the authors also computed that a maximum of 25% Neandertal ancestry into the modern
human gene pool would be compatible with a total lack of Neandertal sequences in living humans. They also noted that the maximum amount of Neandertal ancestry is highly dependent on the specific demographic scenario and the amount of Neandertal ancestry is likely to be even lower, a point also addressed by Currat and Excoffier (2004), who argue that there would have been virtually no Neandertal admixture under a realistic model of range expansion into Europe. It is clear from these two studies that the computations depend critically on the specific demographic scenario used, and further work on incorporating archeological findings needs to be done.

20.4.3 Admixture or replacement of Neandertal DNA?

At present, all available data from ancient DNA analysis point to a relatively low amount of Neandertal ancestry in modern humans, but debate remains as to whether it is zero (as expected under replacement). It may turn out that we will be unable to distinguish between a very low amount of Neandertal ancestry, perhaps on the order of a few percent, and zero ancestry. In either case, we could all agree on the genetic replacement of the Neandertal gene pool for all practical purposes but still disagree on the underlying mechanism of anagenesis versus cladogenesis. It is worth noting in this context that there are some indications from the fossil record that agree with a pattern of relatively rapid (by geological standards) modern admixture into the Neandertal gene pool resulting over time in close to zero Neandertal ancestry in living humans. Wolpoff (1999) presents several examples of traits considered unique to Neandertals that are found in reduced frequencies in the earliest post-Neandertal modern humans. The presence of such traits is perhaps explained by the incorporation of Neandertal genes into an expanding modern human population, particularly given the genetic evidence of a larger population size out of Africa which would “swamp” the genetic contributions of a smaller Neandertal population. Wolpoff also found that these traits had, in many cases, reduced in frequency even further in living Europeans, a pattern suggestive of the cumulative impact of admixture. Additional samples over time and space will be needed to confirm this pattern. We also need to consider the fact that even if it turns out that the Neandertals were replaced in Europe, this does not necessarily mean that the same scenario happened elsewhere in the Old World. Rather than to continue in a debate over replacement versus admixture, we may have to acknowledge the possibility that there was both replacement and admixture events involved in the origin of modern humans and consider evidence, both fossil and genetic, from each major geographic region.
20.5 Application of population genetic models to the fossil record

The final way in which population genetics can contribute to paleoanthropology is in the application of models of population genetics to direct interpretation of the fossil record. Although this approach has not been widely applied, it has great potential in both resolving paleoanthropological debates and potentially uniting geneticists and paleontologists in multidisciplinary studies. Apart from data on contemporary or ancient populations, the field of population genetics has much to offer in terms of helping to frame models and hypotheses regarding the fossil record. Here, I present several examples of such an approach.

20.5.1 Per-generation gene flow and accumulated ancestry

Gene flow generally acts to reduce genetic differences between populations. The degree to which populations are distinct from one another depends in part on the magnitude of gene flow between them, be it local gene flow mediated by isolation by distance or long-distance dispersal. Expectations of the relationship between fossil samples separated by time and space are dependent on rates of gene flow. However, the concept of per-generation gene flow is sometimes confused with the idea of accumulated ancestry over many generations. One example is the prediction sometimes made that multiregional evolution requires greater similarity between fossil samples in the same region over time (e.g., European Neandertals and living Europeans) than between fossil samples in different regions (e.g., early African moderns and living Europeans). At first glance, this prediction seems reasonable given that under multiregional evolution, isolation by distance would result in the greatest amount of ancestry in any generation deriving from the same population a generation earlier. After all, in any given generation it seems most likely that any given individual would choose a mate from within the same population. Although this assumption holds true in many cases for very short periods of time, quite different results obtain for the longer spans of time encompassed even when considering “recent” human evolution. Even a small trickle of gene flow adds up very quickly.

A simple example illustrates the distinction between per-generation gene flow and accumulated ancestry. For this purpose I will use the island model of population structure, the simplest model of gene flow. Assume an “island” with an initial allele frequency of $p_0$ that receives gene flow from a “continent” that has an allele frequency of $\bar{p}$ that remains constant over time, and that this gene flow
occurs at a rate of $m$ per generation. In this simple case, gene flow is in only one direction, from the continent to the island. Each generation, the island receives a fraction $m$ of its genes from the continent and a fraction $1 - m$ of its genes from itself. After $t$ generations, the allele frequency of the island is $p_t = \bar{p} + (1 - m)^t(p_0 - \bar{p})$ (Hartl and Clark 1997). The model shows clearly that given sufficient time, the allele frequency in the island will approach the allele frequency of the continent, a simple case of genetic replacement because as $t$ becomes larger, $p_t$ becomes more similar to $\bar{p}$.

The rate of gene flow ($m$) is for each generation. The other relevant quantity is the amount of accumulated ancestry, $M$, that has occurred in total over the course of $t$ generations. For this quantity, the allele frequency in the island after $t$ generations would be $p_t = (1 - M)p_0 + M\bar{p}$ (Roberts and Hiorns 1962). Combining this equation with the one above gives the relationship $M = 1 - (1 - m)^t$. The main point here is that even given relatively low rates of per-generation gene flow could add up very quickly over time. For example, if the rate of gene flow from the “continent” were $m = 0.01$ for $t = 100$ generations, the total amount of ancestry from the “continent” in the “island” would be $M = 0.63$. For a rate of $m = 0.1$ and $t = 100$, then the total amount of accumulated ancestry would be $M = 0.99997$. It is easy to see how, under the right conditions, that genetic replacement could occur very rapidly and alter the expected pattern of biological distances over time.

### 20.5.2 Gene flow and biological distance

Although the island model is rather simplistic, the general insights obtained with it apply even with more complex migration models (Relethford 1999). The main point here is that predictions of biological distance between fossil samples based on per-generation rates of genetic exchange might be incorrect. In terms of modern human origins, several studies have examined patterns of biological distance across time and space based on cranial measures (Stringer 1993; Waddle 1994; Sokal et al. 1997). The critical biological distances are those between fossil samples over time. For example, under the African Replacement Model, one would predict greater similarity between European moderns and early African moderns than between European moderns and European Neandertals. However, the prediction that any multiregional model would show greater similarity between European moderns and European Neandertals would be incorrect.

As shown elsewhere (Relethford 1999), rates of gene flow and population size affect the predicted pattern of biological distances. Specifically, the population that contributes the most accumulated ancestry over time will determine the
pattern of relationships. As genetic evidence suggests that most (but perhaps not all) of our ancestry comes out of Africa, this means that the greatest similarity over time will be between recent modern humans and early African moderns. Thus, under either the African Replacement Model or the Primary African Origin Model, we expect to see recent Europeans look more like earlier Africans, recent Asians look more like earlier Africans, and so forth. In other words, both models generate the same pattern of expected overall biological distances. Further, the same predictions would be generated for different subsets of the Primary African Origin Model, such as a long-term pattern of interregional gene flow with a larger African population size (Relethford 1999), a pattern of dispersals with admixture out of Africa, or even a combination of these (Templeton 2002).

20.5.3 Regional continuity

Regional continuity, the persistence of traits in a region over time, is central to multiregional evolution and is the primary fossil evidence used to argue against a replacement model. At first glance, however, the previous discussions of the long-term cumulative effects of gene flow out of Africa might seem to contradict the predictions of regional continuity. If, after all, gene flow can alter our expectations of regional similarity in biological distances, then how can we expect any evidence of regional continuity? Should we expect to see gene flow erase regional continuity? No, because regional continuity of neutral traits can be caused by the interaction of gene flow and genetic drift and the fact that gene flow affects all traits, whereas genetic drift can have a different expectation for each trait (Relethford 1999).

Under a Primary African Origin, the gene flow out of Africa would affect all traits equally, and any biological distance measure that is an average of all available traits will show the closer relationship to earlier African samples discussed earlier. Because of the random nature of genetic drift, some traits will retain regional continuity in the face of the overall impact of gene flow. For this reason, we should not expect to see regional continuity for all traits, but instead only a small number of them. The balance between gene flow and genetic drift, whereby drift can oppose the homogenizing nature of gene flow, has long been known, dating back to the classic equations of Wright (1931) for the simple case of the island model. The effect of drift is the same in more complex situations, as shown by computer simulation (Relethford 2001c). These results suggest that we need to examine more closely observed patterns of regional continuity. For example, Lahr (1994, 1996) conducted a comprehensive analysis of regional continuity and found that the majority of traits analyzed did not show
regional continuity, and those that did were not found in any one region exclusively. Although Lahr argued that such findings contradict the claims of regional continuity in recent human evolution, it is clear that these patterns are consistent with regional continuity due to a balance between interregional gene flow and genetic drift (Relethford 1999, 2001c). On the other hand, it seems less likely that patterns of regional continuity would arise from under a replacement model. It thus appears that the dominant signal from the fossil record should not be regional continuity under any origin model, or in average biological distances, but instead show up in lesser degree under any model incorporating admixture. There should be no continuity under a replacement model. However, further work needs to be done in this area to determine if a replacement model with retention of ancestral traits combined with genetic drift could mimic regional continuity. We also need to address the additional complication of sampling error (i.e., we might be missing evidence of a regional trait in other regions because of small sample size).

20.5.4 Hybridization of Neandertals and modern humans

Both the African Replacement Model and the Primary African Origin Model agree that anatomically modern humans first arising in Africa expanded across Europe during the Late Pleistocene. The difference between these two models is that the latter proposes admixture between modern and Neandertal populations. If so, what pattern should we see in terms of Neandertal–modern hybrids? To date, the evidence for such hybridization has been scarce and controversial. The Lagar Velho child has been suggested to be one such example (Duarte et al. 1999; Trinkaus and Zilhão 2002), although others suggest it is simply a chunky modern human child (Tattersall and Schwartz 1999). Another possible example is an early modern human mandible from Romania that shows some archaic and possibly Neandertal features (Trinkaus et al. 2003).

If admixture occurred between Neandertals and moderns in Europe then should we expect to see more evidence of hybridization? This question provides another example of how the application of population genetics models to the fossil record might be useful in determining expected patterns. Although the expectation of hybrids might be rather high under some models of gene flow, more complex models could reveal a different expected pattern. An example in this case is the diffusion wave model (Eswaran 2002), which proposes that modern human populations expanded out of Africa and that this diffusion was due in part to a selective advantage of a modern genotype. The details of this
model involve the movement of a selective wave front where archaic genes are assimilated. For the purpose of illustration here, it is worth noting that Eswaran specifically addressed the issue of apparent hybridization in the fossil record. He noted that hybridization would be apparent only on the wave front and if the process were quick in evolutionary time, there would be little evidence of hybridization in the fossil record. For example, his computations suggest that if modern humans diffused across 3,000 km in 20,000 years, then only 10% of the fossils from that time would be expected to show clear signs of hybridization. If true, we have another example of how the fossil record might not easily discriminate between replacement and admixture models, a situation similar to that with much of the genetic evidence. Whether or not Eswaran’s model holds up under further study remains to be seen. I do not offer it here as the final word, but rather as an example of the kind of input population genetics can have in future paleoanthropological research.

20.6 Some closing thoughts

Molecular and population genetics has made an impact on the study of paleoanthropology and will continue to do so. While early work in molecular anthropology focused on the divergence of African ape and human lineages, the issue of modern human origins has dominated much of the research in the past two decades. Genetic data from contemporary populations continue to accumulate at an increasing pace, and it is likely that the growing abundance of genetic markers will soon allow questions to be answered with greater precision (Wall 2000; Marth et al. 2003). Likewise, additional genetic data on ancient populations could increase our ability to test various hypotheses, such as the maximum amount of possible Neandertal ancestry given a lack of Neandertal-like sequences in living humans (Serre et al. 2004). However, more needs to be done in developing new models and analytic methods that can potentially resolve current problems such as the recent work of Eswaran (2002) and Templeton (2002).

We also need to increase the contribution of population genetics models to the fossil record. Models need to be developed that will provide specific predictions regarding expectations from the fossil record. As noted earlier and elsewhere (Relethford 1999, 2001c), initial predictions often turn out to be incorrect or more complex than once thought. In addition, model building should not be an exercise completed in isolation from the fossil and archaeological records; models must be developed that fully utilize available information on ancient population size, migration patterns, and other demographic data. Perhaps the greatest lesson to be learned from a consideration of the fossil, genetic,
and archeological evidence is that all of these approaches are vital and necessary to truly understand human evolution. I see little point in arguing about which approach is “better” or in ignoring the potential contributions all types of data bring to paleoanthropology.

21 Ancient DNA

Susanne Hummel

Abstract
Ancient DNA research, defined as the retrieval and analysis of DNA sequences from various degraded biological source materials, has promoted many biological and medical research fields during the last two decades. In particular, historical anthropology and paleoanthropology stand to benefit from direct access to backdating genetic data, as has already been shown through applications ranging from individual identification, reconstruction of kinship and marriage patterns to human phylogeny. The DNA-based prerequisites and basic methodological strategies for access to the various types of information are explained, as well as the characteristics of ancient DNA that limit the different approaches. Major restrictions arise from the degradation of ancient DNA down to fragment sizes of at the most only a few hundred base pairs. This fact links ancient DNA analysis almost exclusively to the PCR technique that enables us to deduce genetic information from degraded nucleic acids. Furthermore, ancient DNA extracts regularly consist of only a few intact target sequences, which may additionally reveal sequence deviations due to the degradation process. Both these factors make the analysis vulnerable to the generation of nonauthentic results. These pitfalls of ancient DNA analysis are explained and discussed in detail with reference to the most recent relevant literature. Wherever possible and available, suggestions for strategies to overcome commonly experienced obstacles in ancient DNA analysis are highlighted and evaluated.

21.1 Investigating the past

Today, the analysis of ancient degraded DNA extracted from forensic evidence samples and archeological specimens, hundreds and thousands of years old, is a common practice. It was the coincidence of two events, two decades ago that enabled this remarkable and comparatively rapid development. On the one hand, there were the first reports on the retrieval of ancient DNA from a specimen of an extinct quagga more than 100 years old (Higuchi et al. 1984) and a specimen of an Egyptian mummy 2,400 years old (Pääbo 1984) that electrified many scholars working on historic and prehistoric biological sample materials. On the other hand, PCR was
invented enabling the enzymatic amplification of short specific DNA sequences (Saiki et al. 1985), which proved to be a true breakthrough to a new level of information for any biological and medical discipline. Only through the PCR technique did ancient DNA research, defined as the retrieval and analyses of degraded DNA sequences from forensic evidence, museum specimens, archeological finds, fossil remains, and any other degraded trace of DNA, become viable.

In the context of population genetics, it is in general possible to deduce former states from present day genetic patterns to former states with the help of model calculations (Barbujani and Bertorelle 2001; Cann 2001). However, these approaches may suffer from heuristic assumptions that fail to prove their applicability. Biases may be caused through, e.g., unknown bottleneck situations, unknown selective forces, or the nonreliability of the molecular clock model. Therefore, direct access to historic and prehistoric genetic patterns has been a desideratum ever since ancient mitochondrial and nuclear DNA (nDNA) proved to be approachable through PCR (Hagelberg et al. 1989; Hummel and Herrmann 1991; Jeffreys et al. 1992; Gill et al. 1994).

In the early days of ancient DNA research, the connecting link for scholars from different scientific backgrounds was the fact that the investigations deal with a demanding sample material (Herrmann and Hummel 1993). However, within a short time, the field has diversified and thousands of manuscripts that may be claimed to be ancient DNA research work have been published. Among the various scientific contexts are, for example, epidemiology and public health (for reviews see, e.g., Zink et al. 2002; Greenblatt et al. 2003; Drancourt and Raoult 2005), nutritional sciences and food technology (Miraglia et al. 2004; Kato et al. 2005; Teletchea et al. 2005), histopathology and laboratory medicine (Leiva et al. 2003; Mariappan et al. 2005; Paik et al. 2005), forensic sciences (Iwamura et al. 2004; Valenstein and Sirota 2004; Budowle et al. 2005; Carracedo and Sanchez-Diz 2005; Sipoli Marques et al. 2005; Tamaki and Jeffreys 2005), human evolution (Cavalli-Sforza and Feldman 2003; Kaessmann and Pääbo 2004), paleobotany (Gugerli et al. 2005) and historical anthropology (Keyser-Tracqui et al. 2003; Hummel 2003a). Although the development of scientific questions is increasingly divergent, there is still a strong connecting link in the discussion, the question of authenticity of ancient DNA results.

Proving and disproving the authenticity of one’s own and other authors’ results is the main topic of many of the recent ancient DNA publications. However, the discussion does not include the question of whether particular ancient DNA investigations make sense or are rather an indication of a common trend to involve molecular methods as, for example, one may judge for some of
the Neanderthal investigations (Krings et al. 1997, 2000; Ovchinnikov et al. 2000; Beauval et al. 2005). It is no longer just a claim for paying attention to a list of criteria (Cooper and Poinar 2000) which—according to the authors—have to be obeyed in ancient DNA analysis. Instead, it is most welcome to read that “... the criteria were intended to assist in determining the authenticity of a study, but they cannot replace a crucial consideration of the problem” (Gilbert et al. 2005).

When we take a closer look at the criteria of Cooper and Poinar (2000), it is obvious that they reflect the typical difficulties in the analysis of ancient mitochondrial DNA (mtDNA) in particular from individual or few specimens. However, this type of investigation with its characteristic problems is far from being representative of all ancient DNA based investigations. Nonetheless, the criteria have been regarded as the ultimate solution for any type of ancient DNA investigation for quite some time, although indeed they do not apply, for example, to ancient short tandem repeat (STR) typing or the analysis of large series of samples (Hummel et al. 2000; Hummel 2003a, b).

Finally, at least some of the most recent publications seems to allow reason to prevail and raise differentiated questions, such as how to identify, how to deal with, and ideally, how to overcome results which are due to either contamination or degradation artifacts in ancient mtDNA analysis. Although not literally expressed, this new and positive trend in the authenticity debate indicates that frequently published standard terms corresponding to “... amplification products were absent in the negative controls (data not shown) ...” and “... DNA degradation pattern can be excluded to be responsible for the results ...” are now discovered at best to be wishful thinking at least as far as ancient mtDNA analysis is concerned (Hummel 2003a; Gilbert et al. 2005). However, it is more than irritating to read in the same paper of Gilbert et al. (2005)

▶ ... we encourage the extension of these questions a little further as to ask: ‘Even if I believe that the data might be slightly inaccurate, does this alter the final conclusion of the research?’ For example, although the first published Neanderthal sequences might contain a few damage-induced errors, these would not influence the conclusion that Neanderthal mtDNA is likely to fall outside the clade of modern human mtDNA. By contrast, however, such errors might affect the estimates of Neanderthal coalescence ages by a few ten thousand years and, thus, studies that intend to use the data to this end should take this into account.

With the background that the criteria of Cooper and Poinar (2000) were argued to be the sole basis for valid ancient DNA research (Hofreiter et al. 2001; Willerslev and Cooper 2005), the only possible conclusion is that the criteria were
indeed not solely an expression for the wish of good practice in natural sciences but rather served for science politics strategies to support a self-referential and considerably aggressive peer review system. Further, it is not acceptable to pass down the responsibility for validity of data to those who take them as a basis for scientific deduction (Currat and Excoffier 2004). Nonetheless, the current development which questions the omni-applicability of the list of criteria but favors the adaptation of the experimental design to the actual question (Hummel 2003a; Bandelt 2005) also gives reason to hope for a common understanding that authenticity of ancient DNA results is not ensured through the claim of excellence but through sophisticated experimental approaches.

### 21.2 Ancient DNA sources and characteristics

Genetic information may be preserved in any type of biomaterial which contained cells. In the average animal cell, basically the entire genetic information characterizing an individual is coded in the diploid set of chromosomes and hundreds to thousands of mitochondrial genomes. However, cell organelles may suffer from regular processes of partial or complete degradation already in the living organism, e.g., the decline of the nucleus in keratinous cells of hair and nails during growth. In plants, additionally the chloroplasts contribute to the genomic information. While in plants in particular, seeds are already foreseen by nature to preserve genetic information through time, a similar situation is not present in animals. However, skeletal materials, such as bone and teeth, harbor cells in a more or less intact state of preservation through the ages. Within those tissues that are characterized by a high content of inorganic material and high density, different cell types are DNA sources: osteoblasts, osteoclasts, and osteocytes, which are responsible for bone remodeling and homeostasis, as well as all types of blood cells found in the Haversian canals. Besides the cells representing the genotype of the organism whose skeletal remains were found, additionally cells of pathogens entering the blood stream may be preserved.

Typically, the majority of ancient DNA is degraded down to fragments smaller than 200 base pairs (bp) of length. This can reproducibly be shown through multiplex approaches (Figure 21.1) which simultaneously amplify DNA fragments of different lengths ranging from 100 to 350 bp.

The typical signal patterns observable in electropherograms of multiplex amplifications indicate comparatively high yields of DNA fragments smaller than 200 bp and lesser yields of larger fragments. These patterns are not dependent on possibly varying amplification efficiencies of the different primers of
preferential amplification of shorter fragments but entirely reflect the amount of target sequences. This should be considered when choosing and optimizing PCR parameters.

21.2.1 DNA degradation

Whether the genetic information of an organism will be preserved just for days and weeks or for hundreds and thousands of years depends on many chemical and biological factors that are connected in a highly complex manner and are, therefore, hardly understood and almost impossible to predict. From long-term empiric findings of many researchers and a small number of systematic studies
(Burger et al. 1999), just a few facts favoring the preservation of partly intact DNA seem undisputedly clear: low temperatures and absence of humidity, accompanied by a neutral or slightly basic pH value.

Immediately following death, these conditions are best realized in distal parts of the body, preferably in bones and teeth due to their high mineral content. When the environment of the decomposing body provides an optimal situation, the enzymatically driven autolytic decay is stopped as soon as possible; at the same time the subsequent decomposition of remaining tissues through microfauna, bacteria, and fungi has a reduced chance to effectively take place. The result is a mummification of the cells which, once it has occurred due to optimal environmental conditions, has a good chance to last for thousands of years. The DNA within the mummified cells is now protected from the initial main destructive processes: hydrolysis and the activity of exonucleases and endonucleases. However, DNA will still suffer from destruction (e.g., oxidative damage) although the order of magnitude is less effective than in the course of early decay.

As a matter of fact, the mere preservation of macromorphologically intact skeletal material indicates pH values also favoring DNA preservation. If the pH values had been as acidic as was claimed in a paper that is still often cited (Lindahl 1993) in the context of DNA degradation, the bone mineral would have been turned into the water soluble brushite and thus would no longer have existed.

Further, a more or less intact micromorphology that can be assessed by histological techniques indicates the absence of microorganisms, which is also favorable for DNA preservation.

Finally, most recent studies by the present authors indicate that the amount of preserved DNA seems to be favored not only by the density of the bony material (compact versus spongy bone) but also at the least as much by a distal anatomical region, i.e., far from the torso with its largest amounts of soft tissues. If these findings prove to be reproducible, it would not only be an enormous help in the decision to sample a skeleton but would also indicate that the very initial autolytic processes of body decay are possibly greatly underestimated concerning DNA degradation and long-term DNA preservation.

### 21.3 Information from the genome

All genetic information in a cell is called the genome, independent of its informative value, what type of cell organelle it originates from and its mode of inheritance. In animal cells, the genome regularly consists of two types of DNA
which differ from each other in many respects: chromosomal DNA, also known as nuclear DNA, and mitochondrial DNA. While nDNA is organized in the form of densely packed chromosomes that are located within the single nucleus of a cell, mtDNA is organized in up to 10 identical plasmid-like rings within each mitochondrion of a cell. This is different from the single nucleus in that there are many mitochondria per cell; depending on the intensity of the metabolic turnover of the specific tissue, it may be up to thousands.

Both types of DNA, mitochondrial and nuclear, consist of coding and noncoding regions. The coding regions, also called genes, determine protein synthesis, i.e., they are expressed through the phenotype of an individual, including pattern which can regularly not be seen, such as immunological characteristics. However, up to the present, the noncoding regions of mtDNA and nDNA have been much more the focus of ancient DNA research. This is due to the fact that noncoding regions allow a high degree of sequence and length polymorphism, which are the basis for identifying and reconstructing kinship from the phylogenetic to the genealogical level (Budowle et al. 2003; Pakendorf and Stoneking 2005; Rowold and Herrera 2005).

### 21.3.1 What does mitochondrial DNA tell us?

MtDNA is most suitable for estimating the time of divergence of two or more populations and, for example, for reconstructing migration patterns. This is due to its nonrecombinant mode of inheritance, which implies that all differences found in the mitochondrial sequence are the result of mutation events that are thought to occur in a constant manner (molecular clock). Since the sequence divergence of mtDNA represents a depth of time, it can also be easily understood why it is in principle possible to investigate present day populations in order to reconstruct events deep back in time. Depending on the choice of the sequence that is analyzed, it may allow us to discriminate individuals on the species or subspecies level or to assign the maternal lineage to a certain population.

Factors that are thought to perhaps affect the precision of the molecular clock are changes in the amount of natural irradiation (due to volcanic eruptions) and the question of the number and likelihood of back mutations, particularly at so-called mutational hot spots of the mitochondrial sequence. Additionally, in the analysis of ancient mtDNA, the indications for sequence-specific pseudo-mutations due to DNA degradation, nuclear insertions, and the particular high background of contamination through mtDNA and related questions that throw the authentic nature of the analysis result into question must be considered.
21.3.1.1 Inheritance of the mitochondrial genome

The mitochondrial genome is inherited maternally, lacking recombination and therefore representing a so-called haplotype. This is due to the fact that each female oocyte possesses a full set of mitochondria, while the sperm needs just a few to generate energy for movement. For quite some time, it was thought that mitochondria of the sperm did not enter the oocyte at all, but there is evidence that male mitochondria do enter but are identified as foreign and destroyed by the oocyte. If this process is not effective, the result is a so-called heteroplasmy, i.e., two different sequences with its particular sequence deviations are represented in an individual’s mtDNA. Heteroplasmy may also derive from replication errors during cell duplication, a phenomenon particularly often observed and well known from particular C-stretches of the hypervariable regions (Malik et al. 2002). In ancient DNA analysis, it may be challenging to distinguish between a true heteroplasmy and an artifact signal that may occur due to various reasons.

21.3.1.2 Sequence polymorphisms

MtDNA reveals a comparatively high density of genes. In humans, as many as 37 genes are represented within the total length of 16,569 bp of a single mtDNA genome. Most of these genes are involved in the metabolic turnover of the cell. Due to the nature of a gene, which codes for the synthesis of proteins, only very limited sequence deviations are possible if a nondisturbed function is to be reached. However, there are two regions within the human and animal mitochondrial genome, so-called d-loops, which are noncoding, i.e., not involved in protein synthesis. One of the d-loops, almost spanning about 1,000 bp at the nomenclatoric origin of the mtDNA, is also known as the hypervariable region (HVR) revealing comparatively extensive sequence polymorphism. Besides base exchanges, there may also be base deletions and base insertions. The sequences of two randomly chosen individuals from a population differ on average at eight nucleotide positions within the HVR. The experimental design in ancient DNA analysis from prehistoric specimens must consider possible further deviations that may lead to mismatches in the primer binding sites causing amplification failure.

21.3.1.3 Cambridge reference sequence

In order to describe the deviations unambiguously, the international scientific community has agreed to refer to a certain reference sequence. This sequence is
either known as the Cambridge reference sequence (CRS) or the Anderson reference sequence. This represents the entire sequence of a human mitochondrial genome, the first that was ever analyzed entirely (Anderson et al. 1981). However, the originally published sequence obviously reveals some rare polymorphism and sequencing errors (Andrews et al. 1999). The sequence belongs to an individual of haplogroup H, which is the major haplogroup in individuals of European descent. Since in phylogenetic terms this of course does mean that it is a comparatively young sequence pattern, there are fairly many nucleotide positions in the human mtDNA that are different from the CRS in all other haplogroups found worldwide. Moreover, the CRS reveals two comparatively rare deletions in C-stretch regions of the HVR II, which means that the length of the average human mitochondrial genome is 16,570 or 16,571 bp, respectively.

21.3.1.4 Haplotypes, maternal lineages, and haplogroups

The actual base sequence in the HVR of an individual is named as haplotype and represents the pattern specific to a maternal lineage. All individuals sharing this haplotype are members of the same maternal lineage, i.e., they are directly related in a genealogical sense, which is most likely when the haplotype is rare or even unique. Alternatively, they are at least closely related in a population genetic sense, e.g., when many people who are not known to belong to the same genealogical family share this haplotype.

The sequence differences found worldwide in the highly polymorphic HVRs of the mitochondrial genome are divided into more than 20 haplogroups consisting of further subgroups. Those groups are clusters of sequences revealing high intragroup similarities. In general, the assignment of a sequence to a certain haplogroup depends on actual bases that are present at certain key nucleotide positions. While more than 95% of individuals of European descent can be ascribed to one of seven major haplogroups (Richards et al. 1998), a similar percentage of Native Americans are ascribed to four haplogroups (Torroni et al. 1993). Particularly within far branching out ancient haplogroups, a further division into subgroups is common. Again the subgroups are defined through an additional base pattern at further nucleotide positions that is shared by all representatives of the subgroup. Since ancient DNA is suspected to promote the generation of pseudo-polymorphisms, preferably following a particular base sequence pattern due to degradation artifacts, the interpretation and deductions with respect to phylogeny and migration from the occurrence of rare or novel haplotypes must be done with care.
21.3.1.5 Phylogeny and migration

The age and spread of haplogroups enable us to draw conclusions to questions of phylogeny and migration pattern. The age of a haplogroup is basically deduced from its heterogeneity, i.e., the degree of sequence variation within the group. Basically, haplogroups that are more widespread and reveal more different branches and subgroups are older than those that are comparatively homogeneous (Figure 21.2).

In this manner, it is also possible to determine the regional origin and migration patterns of a haplogroup, which is represented over a geographically widespread area. At the place or region where representatives of the haplogroup originate from, the sequence diversity is expected to be higher than in any other region where the haplogroup is found (Watson et al. 1997).

21.3.2 What does chromosomal DNA tell us?

The analysis of chromosomal DNA sequences allows access to the unique genetic pattern of an individual. This pattern is represented through the specific

![Figure 21.2](image-url)
combination of single polymorphic genetic traits, which characterize the individual on a level that enables identification. The number of genetic traits that must be observed to enable identification depends on the degree of polymorphism that is recorded for the observed traits. Most common for identification purposes that are the basis for, e.g., the reconstruction of genealogical kinship, are so-called STRs. Those markers reveal a comparatively high degree of polymorphism, i.e., on average 5–15 alleles of varying lengths are present in a population for each STR. These markers are also suitable for population genetic purposes, although data of many individuals are necessary in order to enable conclusions with respect to phylogeny and migration.

Another target are single nucleotide polymorphisms (SNPs), which are usually biallelic markers revealing a sequence polymorphism at a certain nucleotide position. Unlike STRs, they are not investigated to reconstruct kinship, although this would be possible in principle, but in order to, e.g., determine the immunological properties of an individual. Since immunological properties of a population are subject of strong selective forces through the presence of pathogens influencing morbidity and mortality rates, regional and/or diachronic changes of allelic frequencies of SNPs allow us to draw conclusions to questions such as the spread of epidemic or pandemic events and living conditions.

In ancient DNA analysis, the accessibility of chromosomal markers is restricted through the comparatively low numbers of originally present genomes in a given sample volume. However, optimizations of DNA extraction protocols may indeed compensate for this disadvantage. Once successfully extracted, the analysis of nuclear markers is much less prone to erroneous results due to contamination given a careful experimental design.

21.3.2.1 Inheritance of the chromosomal genome

The chromosomal genome of an individual represents a novel and unique recombination of its parental organisms. Both parents contribute a so-called haploid set of chromosomes which are randomly composed from their own diploid chromosomal sets. Therefore, each locus under investigation reveals a maternal and a paternal allele. As soon as it comes to the analysis of coding regions, the genotypic level may often be determined without difficulties, but this does not necessarily hold true for the phenotypic level. Gene expression and suppression must be known in order to allow conclusions to be drawn from the analysis of the genotype of an individual to its phenotype. In ancient DNA analysis, a particular situation that is suspected to be involved in
the context of many diseases remains unsolvable: the phenomenon of compound heterozygocity. Compound heterozygocity describes the situation that two (or more) mutations, distant from each other on the same chromosome and responsible for a certain morbidity risk, have to be present in a heterozygous state, but one mutation must be located on the maternal, the other on the paternal allele. In ancient DNA with its highly fragmented target sequences, compound heterozygocity cannot be discriminated against a heterozygous state where both markers are mutated either on the maternal or the paternal allele.

### 21.3.2.2 Length polymorphisms and sequence polymorphisms

Chromosomal DNA consists of coding and noncoding sequences. From the human genome sequencing project it is known that the majority of DNA is noncoding, sometimes called junk DNA. Within the noncoding DNA about 20–30% of the DNA consists of tandem repeated sequences. Some of them, STRs, are particularly interesting since a set of them enables the genetic identification of an individual. The alleles reveal length polymorphism which is a function of the number of repetitions of the core unit. In fact the short repeats are often identical (e.g., CA$_n$ or AGAT$_n$), but the unique nature of the neighboring sequences enables us to specifically target a certain STR locus. Other than sequence polymorphisms, the variations in fragment length are not suspected to suffer from specific DNA degradation leading to a result that, although reproducible, is still erroneous. However, ancient DNA analysis must be carried out carefully since STR amplifications also reveal typical so-called stutter artifacts. Since stutter bands occur stochastically, the artifact can be overcome through multiple analyses. Further, the occurrence of this typical artifact can be minimized through optimization of DNA extraction and a sophisticated choice of PCR parameters. The multiple analyses also prevent erroneous homozygous results, which may occur due to so-called allelic dropout when only a small number of intact target sequences are present.

The analysis of ancient DNA SNPs which are spread throughout the genome, has basically to deal with the same pitfalls that are suspected of affecting the analysis of mitochondrial sequence polymorphisms. Although the risk of nonauthentic results due to contamination is much lower than in the analysis of mtDNA and, moreover, can efficiently be monitored through a suitable experimental design, the risk of false results due to specific degradation pattern must be considered in the same way as in mtDNA analysis.
21.3.2.3 Genetic fingerprints and identification

The specific allele combinations from analysis sets consisting of 5–15 STRs are also known as genetic fingerprints. As the name implies, the specific allele combinations have an identifying character. Genetic fingerprints are suitable for genealogical kinship reconstruction and for the identification and the assignment of skeletal elements.

In order to be suitable for genetic fingerprinting, the STRs combined in a set have to fulfill two major prerequisites: first, they must be located on different chromosomes in order to avoid haplotypes and to ensure a recombinant mode of inheritance. Second, they must not be linked to genes in order to avoid the force of possible selective pressure, which would be indicated by strong deviations from a Gaussian allele distribution. If these criteria are fulfilled, the value to which the so-called matching probability (Pm) can be determined depends on the total number of STRs investigated and on their respective allele frequencies in a given population. The Pm is defined as the likelihood that a second nonrelated individual reveals the respective allele combination just by chance. Typical Pm values for commercially available and customer-designed sets consisting of 9–15 STRs range from 10^{-10} to 10^{-24}. Of course, these impressive values apply to ideal populations only (panmictic, no selective pressure, etc.). However, the situation in real, possibly even inbred populations, can be simulated approximately when calculating the value that given parents will give birth to two children revealing the same genetic fingerprint. If 10 STRs are observed, the likelihood of this event ranges from 10^{-5} to 10^{-7}. These values indicate that individuals from an inbred population with a limited gene pool are still discriminated on a sufficient level.

The identifying properties of genetic fingerprints also indicate that STR typing is more suitable than any other strategy to identify possible contaminations from a wide spectrum of sources.

21.3.2.4 Reconstructing kinship and paternity testing

The reconstruction of kinship in a (pre-) historic skeletal series requires a different strategy, as if it were a living population. While in a living population, the individual age helps to a priori discriminate the parental generation from the potential descendants, this information is not available in a skeletal series. It is possible to find the skeletal remains of an individual who died in his early adulthood who fathered an individual who reached the senile age class. Although individuals who are related vertically at first degree share an allele for each
observed genetic marker, it is not possible to deduce who is the parent and who is the infant from the genetic markers. Therefore, infant individuals who have not reached reproductive age play a key role in the reconstruction of kinship (Figure 21.3).

If two individuals are found to share an allele for each STR system (=STR 1, STR 2, and STR 3), they may be parent and child. (a) From the STR typing and the Y-Haplotype (=Y1), it cannot yet be deduced who is the father and who is the son. (b) A morphological or histological age determination not only solves this problem but moreover enables us to predict the genotype of the mother who is still missing. (c) If a female individual is found who reveals the respective STR alleles as well as the suitable mitochondrial haplotype (=mt J), she can be assumed to be the mother. The likelihood of parentage can now be calculated based on the allele frequencies of the investigated STRs.

If two individuals—infant and adult—are found to share exactly one allele at each observed locus, a paternity (or maternity) test can be calculated as a deficiency case (i.e., one parent missing). If the allelic genotype of a second adult individual of the opposite sex suggests that this may be the missing parent, the likelihood of parentage for both assumed parents is calculated in the manner of two independent trio cases (Brenner and Morris 1990; Chakraborty and Jin 1993). This means that, e.g., at first the child–mother dyad is taken as fixed, enabling us to calculate the paternity index for the male individual, and then, in an analogous way, the maternity index is calculated.
In particular, if individuals from a larger burial site are investigated with respect to their genealogical relatedness, the initial search for possible child–parent dyads is facilitated by mitochondrial and Y-chromosomal haplotyping. This strategy allows an assignment of individuals to family lineages. Analogous to autosomal genetic fingerprinting, Y-haplotyping is carried out through STR allele amplifications at the Y-chromosome.

21.3.2.5 Immunogenetics and epidemiology: Toward phenotype

The analysis of nuclear genetic markers that are known to be linked to the immunological properties of an individual is comparatively new. Usually these properties are represented through SNPs which cause changes in the amino acid chain, therefore changing protein synthesis. Many of the markers are directly linked to the susceptibility of an individual to bacterial and viral infections and, as a consequence, to the susceptibility of certain cancerous growth. Furthermore, these markers are seen in the context of heterogeneous reactions of individuals to pharmacological treatments.

The allele frequencies of the markers exhibit considerable deviations worldwide, suggesting that selective pressure is responsible, as well as genetic drift and bottleneck situations. It is striking that particular European populations or individuals of European descent often reveal allele distributions that deviate very strongly from all other worldwide human populations. Not surprisingly, this is interpreted as a result of the particular European epidemiologic history during the past centuries and the selective forces that are linked to epidemic and pandemic infectious diseases events (Scott and Duncan 2001).

Many theories and hypotheses that claim to be able to name the particular historic epidemic event that is assumed to be responsible for uncommon allelic distributions are based on more or less profound linkage studies carried out on modern populations (Stephens et al. 1998; Rannala and Bertorelle 2001). However, some must be classified as mere speculations (Altschuler 2000). In any case, all studies lack direct proof. Therefore, the direct access to historic and prehistoric genotype will be invaluable. In particular, skeletal series that are known to be linked to epidemics or pandemics have an important role as genetic archives. Since the burial sites of respective skeletal series are often mass graves (e.g., plague victims), in particular, the possibility of ancient cross-contaminations due to the special burial conditions must be considered when setting up the experimental design.
21.4 Authenticity

The authenticity of an ancient DNA analysis result may be questioned due to two reasons: first, one must exclude the possibility that a contamination is responsible for the outcome of the analysis, and second, it must be proven that the result indeed represents the authentic genotype of the (pre-) historic individual and is not biased through DNA degradation or analyses artifacts. Depending on the scientific question, the actual sequence that is under investigation, the number of individuals investigated, and finally the origin of the samples, proving the authenticity of the ancient DNA analyses results may require entirely different strategies in the experimental design.

21.4.1 Contaminations

Since ancient samples usually consist of very few DNA targets, even very minor contaminations may cause false results. Contaminations may originate from various sources and may reveal various degrees of degradation. Therefore, there is no simple strategy for how to avoid and detect them.

Basically, one can subdivide four ways in which contaminations may enter the analysis:

- Cross-contamination between the ancient sample materials
- Contaminations of the sample material through former or recent investigators
- Contaminations in laboratory reagents and disposable material and
- Contaminations of either sample materials or reagents through amplification product carryover from earlier PCR analyses

21.4.1.1 Cross-contaminations

Cross-contamination of the sample material may in general happen at any time. However, two situations in particular are suspected to increase the risk of sample cross-contamination: burials at a nonindividual site (e.g., mass graves) and the laboratory processing of the samples (e.g., transfer of sample material through nonclean laboratory devices or handling mistakes). Cross-contaminations are particularly hard to detect, since all sequences involved would reveal a degradation pattern as expected for ancient DNA. Further, their occurrence cannot be
identified through the classical set of negative control samples, which includes no-template controls and extraction blanks. A possible cross-contamination event must therefore be recognizable in the analysis result itself, for example, through the amplification of DNA fragments, which would clearly indicate a second individual, e.g., three or four alleles instead of one or two.

21.4.1.2 Contamination through investigators

This type of contamination may in general happen at any time when a sample is handled. What the contamination patterns look like depends on the amount of contaminating cells and whether this contamination happened most recently or decades ago. It may vary from comparatively easy to identify fully intact DNA profiles to a hard to recognize type which resembles the typical cross-contamination. As in the case of cross-contaminations, negative control sample sets are not suitable for monitoring this type of contamination. Again, the analysis result itself must reveal indications for the possible contamination. Other than in the case of a classical cross-contamination, the contamination through an investigator is most likely (but not necessarily) a superficial one. Therefore, thoroughly removing the surfaces minimizes the risk of this contamination type.

21.4.1.3 Contaminations in laboratory reagents and disposables

Laboratory reagents may be already contaminated when purchased (e.g., primers, reaction mixes) or through handling by the investigators. In both cases, the degradation patterns of the contaminating DNA and the amount of contamination may vary strongly. If premixed reaction components are used, particularly bovine serum albumine (BSA) which is a component enhancing the Taq DNA polymerase may cause severe problems due to revealing residues of bovine DNA. This can be shown through cytochrome $b$ sequence amplifications that indicate the species. However, this type of contamination can be monitored through suitable sets of negative controls. Ideally, also the analysis result from the sample material itself provides information indicating possible contaminations.

The situation is completely different if laboratory disposable materials are concerned. Regularly, PCR reaction tubes turn out to be contaminated right from the production process, with human DNA prevailing (Hauswirth 1994; Schmidt et al. 1995) although DNA of bovine origin was already proven (Hummel 2003a).

The percentage of reaction tubes that suffer from contamination varies depending on the supplier, the brand, and the actual lot. The vast majority of
these contaminations are of mitochondrial origin. The reason for this lies in the production process, which very often includes autoclaving steps. If there are just a few reaction tubes containing cellular contaminations at this stage of the manufacturing process, these cells become lysated through the autoclaving temperature and the hundreds of thousands of mitochondrial genomes are distributed more or less uniformly. Typically, the number of tubes that show specific signals of mtDNA after 40 amplification cycles varies between 20% and 80% if fragments of less than about 150 bp are amplified.

The reason why the autoclaving step is still part of the manufacturing process, in particular in so-called high-performance (e.g., “PCR clean”, “DNA free”) and high-price brands, is that in this way the companies are able to guarantee to stay below a certificated level of DNA for each tube in the lot but need not invest in the cost of a truly DNA-free manufacturing process.

All kinds of treatments applied to amplification reaction tubes (e.g., UV treatment, bleaching, rinsing with and without ultrasonic treatment) are inefficient in the sense that they cannot overcome the problem. At best, more or less considerable reductions of the number of tubes revealing contaminations could be reached. Since the contaminating mtDNA in reaction tubes consists of just a few targets per tube and because it is typically just as degraded as ancient DNA, it is usually not even noticed in modern DNA applications.

For ancient mtDNA applications, which may also start from just a few intact targets, it is the most severe contamination problem since it is unavoidable and hard to detect. Typical sets of two or three negative controls are noninformative, simply due to their small number. If they stay blank, this is not necessarily representative for the tubes in which the samples were processed. If the negative controls reveal signals, however, this also cannot be assumed to apply for the tubes in which the samples were analyzed.

The only way to improve the situation in mtDNA analysis is through numerous reproductions of the analysis, ideally amplifying only fragment lengths considerably longer than 200 bp. In order not to have to turn down too many analysis results, which reveal ambiguous signal pattern and are suspected of deriving from the mixture of precontaminating tube DNA and ancient sample DNA, it is recommended to carry out checks with at least 30 negative controls each time a new lot of reaction tubes is in use.

Another way, although extremely laborious and inconvenient, is the use of glass tubes, handmade from high-temperature-resistant glass. They can be reused after being tempered for a couple of hours at 600°C at least. It may be necessary to elongate amplification cycle steps for efficient reactions carried out in glass tubes which, however, are positively contamination-free if the tempering is carried out.
21.4.1.4 Contamination through product carryover from earlier PCR

Product carryover, although a disaster if it occurs, is not a particular threat to ancient DNA analysis. This is because it is comparatively easy to detect and easy to prevent if some basic rules are strictly followed.

Potential product carryover would strike through the easy and low-cycle amplificability of a certain marker, while other markers of similar fragment length would not yet be amplifiable. Also, as long as not only a single sample is contaminated (which is extremely unlikely in the case of product carryover), a series of samples would reveal identical analysis results if, e.g., an extraction buffer was contaminated. If product carryover found its way into a PCR reagent, the entire set of negative controls would all show signals, thus reacting in exactly the same way the samples do.

A way to efficiently prevent product carryover contaminations, which is practiced in almost every ancient DNA laboratory, is the strict separation of pre- and post-PCR areas including a strict dedication of all devices such as pipettes, centrifuges, deep freezers, and any other instruments.

21.4.2 Degradation and analyses artifacts

Ancient DNA results may be nonauthentic due to degradation and analysis artifacts. Even though the authentic ancient DNA has been analyzed, the original sequential order of bases or the original fragment lengths may be biased. If one would just count the publications that report about degradation phenomena, one might believe that nonauthenticity due to degradation artifacts is a critical point concerning almost exclusively the base sequence (Gilbert et al. 2003; Binladen et al. 2006). This is most likely a bias as well, since only very few ancient DNA working groups have experience with fragment length analysis, which again is mainly linked to autosomal and Y-chromosomal STR typing (Keyser-Tracqui et al. 2003; Hummel 2003a). The main discussion of typical fragment length artifacts is therefore led in the forensic sciences context, where STR typing of degraded DNA samples is routine (Butler 2001).

20.4.2.1 Nonauthenticity of the base sequence

Base degradation is one of the major reasons why the analysis of authentic ancient DNA may nevertheless reveal erroneous results. The most numerously occurring artifacts are reported to be the transition C > T/G > A and A > G/T > C, while
others have been observed much more rarely or did not occur at all (C > G/G > C), at least in nDNA (Binladen et al. 2006). Another important aspect is the question of whether mtDNA and nDNA are affected to the same extent by this artifact. Although nDNA is thought less likely to suffer from degradation artifacts due to the better protection of the nucleic acid sequence through the histones, the investigations of Binladen et al. (2006) could not detect major differences. Due to its obvious relevance, the C > T transition is mainly discussed with respect to the cause of the artifact (cytosine may degrade to an apparent uracil, of which the complementary base is an adenine, which again would lead to the introduction of a thymine during the next elongation phase), its likelihood of occurrence and methods to overcome the artifact. One common strategy to prevent the amplification of DNA fragments consisting of apparent uracils is an enzymatic treatment of the DNA extract prior to the amplification (Haak et al. 2005). This strategy claims to destroy all DNA fragments that contain uracil-like degraded cytosines, which may indeed result in total destruction of all potential targets DNA sequences for the intended amplification. However, this does not necessarily mean that all the respective nucleotide positions consisting of a cytosine suffered from quantitative degradation. Further, transitions others than the C > T transitions are not reached through this approach.

Therefore, other strategies to overcome nonauthentic results due to DNA degradation would be preferable, if available. This could be valid strategies for DNA repair or unbalanced initial PCR employing a single primer that results in a linear amplification of one strand only. Further, in the case that the sample itself does not represent a mixture of DNA from different individuals, a combination of cloning strategies—which often suffer from too few clones being analyzed (Bower et al. 2005)—with direct sequencing could be informative.

Another way to monitor and evaluate analysis results that are suspected of being biased through degradation artifacts could be the implementation of cross-checks through amplification of further loci, which basically provide the same information or at least parts of this information. In the case of mtDNA haplotyping, this might be the analysis of SNP markers on the mtDNA genome, which are known to be linked to haplogroups (Torroni et al. 1992). In the case of nuclear SNPs, this may be additional polymorphic sites, which are also known to be linked to certain genes although possibly with a lower linkage rate.

### 20.4.2.2 Nonauthenticity of the fragment lengths

Typical fragment length artifacts are so-called stutter-bands and allelic dropout. Both are artifacts that occur in the course of STR amplifications and are well known
and extensively discussed throughout ancient DNA and forensic literature (Butler 2001; Hummel 2003a). Unlike sequence degradation, allelic dropout and stutter artifacts are not a direct degradation phenomenon but rather an indirect one, since their likelihood of occurrence depends on the number of intact targets that are submitted to amplification. Although the reduced amount of intact targets is characteristic for ancient DNA extracts, the artifacts occur as well in modern intact DNA amplification with few targets throughout the first amplification cycles. But even when very few targets are submitted to the reaction, the generation of this type of artifacts remains a stochastic event that is—other than in the case of base degradation—not due to alterations of the target but an amplification artifact. Consequently, the mere multiple repetition of the analyses enables us to evaluate the authenticity of a result on the basis of the reproducibility. Additionally, there are further strategies to positively influence the tendency of the amplification reaction to create these types of artifacts. The most obvious one is to optimize the DNA extraction in order to increase the number of targets. This in particular helps to avoid allelic dropout. In order to minimize the generation of stutter bands, the relaxation of the elongation temperature has proved to be successful. Since the Taq DNA polymerase activity is negatively influenced through the measurement, the time given for elongation must possibly be prolonged.

In any case, the fact that STR amplifications are regularly carried out in multiplex approaches means that cross-checks are built into the analysis, since the evaluation of authenticity is clearly simplified through the patterns of the entire set of loci amplified (Figure 21.4).

### 21.5 Basic strategies in experimental design

There is no general strategy for how to carry out an ancient DNA analysis, but the most determining factors for the experimental set up are the sample material itself, the scientific question, and the properties of the DNA sequence in focus. These factors should be considered in making the decision for possibly necessary preexperiments (e.g., check for contamination rates in amplification tubes), the choice of appropriate sets of negative and positive controls, and the design of the amplification and analysis strategy.

The final experimental strategy ideally combines two aims: the greatest likelihood to achieve a result that at the same time can positively be proven to be authentic (Figure 21.4).

Since authenticating results are achieved through entirely different strategies depending on whether for example human or animal DNA is under investigation, or, whether a single sample or series of samples are analyzed, whether
mitochondrial or nDNA is the target, or whether base sequences of fragment lengths carry the information, it is obviously unnecessary to discuss the criteria for ancient DNA analysis (Cooper and Poinar 2000), since they do not consider any of the differences mentioned and are therefore overemphasized. An experimental design following these published regulations would most of all match the analysis of human mitochondrial HVR DNA from a single sample. But even for this particular application, following all criteria and regulations does not result in...
a full proof of authenticity since cross-contaminations and contaminations through earlier investigators cannot be ruled out.

21.5.1 Sample preparation

The sample preparation has to be devoted to two main targets:

- To remove possible contaminations and
- To prepare the sample as optimally as possible for DNA extraction and further amplification reaction.

The first aim may only be achieved in the case of superficial contaminations, i.e., most commonly, contaminations of present or former investigators. If the surface of the sample is removed profoundly, the risk of this type of contamination is minimized. How the second aim is achieved depends on the sample material. However, in general, any increase in surfaces through, e.g., crushing the sample prior to a chemical treatment has proven to improve later analysis results. Further, depending on the actually chosen extraction technique, also parameters, such as centrifugation forces and the relation of sample material to incubation buffers and reagents, are crucial. It is recommended to optimize a standard protocol with respect to given sample properties before valuable sample material is processed.

21.5.2 Optimizing DNA extraction

Optimal DNA extraction protocols are obviously a highly individual matter depending on the exact biochemical state and composition of the sample material. However, standard protocols are valuable to start from. Basic aims for standard protocols are

- To maximize the amount of DNA
- To minimize DNA degradation in the course of the extraction procedure and
- To minimize inhibiting substance residual in the DNA extract

At present, these goals seem at best to be achieved through an automated DNA extraction using magnetic beads, although the amount of DNA in the extracts stays somewhat behind, e.g., phenol–chloroform procedures. However, the advantage of the DNA extracts being practically free of inhibitors, as can be demonstrated through real-time PCR, outbalances a possible loss of DNA. In
general, the use of any type of automation at this stage of sample processing is advantageous since the handling of samples is minimized and thus the risk of introducing contaminations.

21.5.3 Amplification strategies

In general, there is no optimal amplification strategy, but the basic experimental design must be deduced from the scientific question and the sequence in focus (Figure 21.4). However, there are some primary aspects which should be considered.

- The more polymorphisms are characteristic for the investigated sequence, the lesser cross-checking experiments are necessary. Ideally, the amplification result is individual in the sense of identifying since this enables an efficient check for any type of a possible contamination event. If, for example, nuclear STR typing is carried out, only a minimum of negative controls is necessary. It may be recommendable to deviate from classical amplification parameters, in particular concerning the elongation temperature. A decrease in the elongation temperature or the shift to a two-step PCR consisting of a denaturing and a prolonged annealing phase only may result in a remarkable decrease of stutter-bands, which is an STR-specific amplification artifact even in modern DNA amplifications.

- If the markers of interest are polymorphic but far from revealing results specific for an individual. In this case (e.g., any type of biallelic SNPs or short deletions), the aim should be to link the result to an identifying one. This is realized through integration of the primers for the, e.g., SNP amplification to a multiplex assay designed for STR-based genetic fingerprinting. This has proved successful for nuclear markers (Bramanti et al. 2000; Fulge 2005; Hummel et al. 2005; Puder 2005), although it may require multistage fragment-length determinations including a restriction fragment length polymorphism (RFLP) analysis. If the biallelic markers are multiplexed with nuclear STRs, only a minimum set of negative controls is necessary.

- The amplification of mtDNA, which is regularly represented in ancient DNA extracts by more intact targets, is hard to carry out in the same approach with the amplification of nDNA. One reason is the different demands for optimal amplification cycles. Moreover, the aim of mtDNA investigations is usually a sequence analysis which—due to technical reasons—cannot be
combined to STR typing. Prechecks of contamination rates for different brands of amplification tubes are highly recommendable. They should be carried out with the primers that are intended for the actual investigation using high cycle numbers (>45). In general, the amplified sequences should be as long as possible (preferably >250 bp) due to the observed decrease of intact contaminating targets. The primers should reveal sensible mismatches against species that are not intended to be amplified but are suspected to be present as contaminating targets (human, working animals). It may be necessary to launch experiments that check sequence specific degradation patterns. Although mtDNA is regularly represented by more targets than chromosomal DNA in an ancient DNA extract, the given situation concerning degradation pattern and contaminations in amplification tubes complicate the proof of authenticity remarkably. Due to these facts and the nonindividual character of the polymorphisms, even in the HVRs of mtDNA well-adapted sets of negative controls are necessary, since typical sets of negative controls do not apply.

### 21.5.4 Enhancing specificity and sensitivity of a PCR

The specificity of a PCR, i.e., the exclusive amplification of the targeted sequence, is a basic prerequisite, in particular if the following analysis includes a so-called Taq cycle sequencing reaction. However, any other type of ancient DNA analysis suffers from the generation of unspecific by-products as well. This also holds true even if no confusion with the targeted sequences is possible due to, e.g., entirely different fragment lengths. The reason for this is a decrease in sensitivity as soon as by-products including primer dimers are generated in the amplification reaction, since the resources for the reaction (Taq polymerase activity, primers, dNTPs, and buffer) may be exhausted through this competitive situation. The consequences are that the targeted product may—although present—not or only weakly reach the detection limit, since the by-reaction already causes the attainment of the amplification plateau.

Although an optimization of the annealing temperature positively influences the specificity of the amplification reaction, however, a highly specific reaction may even so not be reached or compromise the reaction efficiency if the annealing temperature approaches the melting temperature of the primers.

A particularly valid instrument to increase the specificity and therefore the sensitivity of the reaction is given through primer design.
The criteria for a good primer design are

- The primers should reveal a minimum length of 20 bp if possible, preferably 23–30 bp
- The binding energy of the 5’-end must increase the one of the 3’-end in order to enable elongation only if the entire primer matches
- 3’-end primer dimers and hairpin formation must strictly be avoided since these formations are elongated causing generation of by-products
- Should not reveal mismatches to the intended target within at least 3 bp from the 3’-end

If these demands can be fulfilled for a primer pair, the amplification products considerably increase in quality and quantity.

22 Paleodemography of Extinct Hominin Populations

Janet Monge · Alan Mann

Abstract

This review is concerned with a critical evaluation of the paleodemographic studies of the hominin lineage prior to the development of agriculture. Because of the potential this research has for the generation of data about birth spacing, mortality, life span, sex ratio, patterns of fertility, and maturation, the study of the demography of earlier human populations has attracted much attention. The very limited and fragmentary sample sizes, however, combined with many uncertainties about depositional patterns have resulted in major difficulties in the development of generally accepted hypotheses. An additional problem involves the choice of comparative samples for these extinct hominins. Are the data from chimpanzees or modern humans more appropriate in these reconstructions?

Published reevaluations of a number of widely accepted concepts, such as the simple association of life history variables with structures like gross body or brain size, have made them increasingly untenable. Recently collected data on modern humans and free ranging chimpanzees cast some doubt on the idea that these two primates have different timing in their maturation and life span. Some life history parameters, however, such as potential life expectancy, time at maturation, and age at weaning, may very well be amenable to more complete understanding.

22.1 Introduction

Demography is the study of population structure, its size, composition, and related features such as sex, age, geographic distribution, and other environmental, social, and cultural factors. The successful application of demographic studies in modern human societies relies on the accumulation of data on all members of a population or, more commonly, on a calculated sampling of the population (Yaukey and Anderton 2001). In contrast, paleodemography has been characterized
as the field of inquiry that attempts to identify demographic parameters from past populations derived from archeological contexts (Hoppa 2002 p 9) and is primarily based on the analysis of human skeletal materials. The preservation of human skeletons in contexts of even the relatively recent prehistoric past, where agriculture and permanent settlement are present, is variable and dependent on environmental conditions such as soil type and pH, climate, and destructive geological events. Additionally, cultural factors, such as cremation, cannibalism, mass burials, indifference to the disposition of dead infants, and many other behavioral factors also dramatically influence the preservation of human bones. The present review is limited to an examination of the paleodemography of our earlier ancestors, prior to the development of agriculture.

Reconstructing population structure from this more distant past is much more problematic. Preagricultural hominins, it has been postulated, relied on a subsistence base founded on the gathering and collecting of wild foods, insects and small vertebrates, and the hunting of larger animals. Scattered and seasonally available food sources meant that for the most part, these peoples did not have permanent settlements. Rather, they established temporary camps, exploiting the local resources and moving on when these were depleted. The duration of a stay at a particular locale was dependent on the season, abundance of resources, size of the group, and other variables. The groups were small in size (Weiss 1973) often no larger than 30–50 individuals. Temporary encampments and continuous movements imply that deaths would have occurred at different places and that, except for unusual circumstances, we should not expect to find remains of a number of individuals at a specific locale. The expectation is that many deaths will occur during movements and the body left or interred, along the route. Further, deaths would have been seasonal, occurring during those times of the year when resources were scarce; this implies that hominin remains are more likely to be found at some locales and not others. These generalizations about early members of the human lineage, however, are overwhelmingly based on the anthropological study of living gatherers and hunters, and the accuracy of these observations when applied to earlier, now extinct humans, is uncertain. There is, for example, no certainty that all earlier hominins actually were gatherer/hunters; they may have been more specialized in dietary choice and habitat and thus were organized in a different but unknown fashion. As there are periods in the hominin fossil record which indicate that multiple hominin species coexisted, perhaps in geographically close proximity, it remains possible that early hominin demography was based on very different adaptive patterns. Further, prior to about 115 ka, the sample of hominin skeleton bones available for study is very small. Only after this time did the introduction of the deliberate burial of the dead result in many more bodies being preserved, and numbers of more or less
complete skeletons excavated. Finally, study of the earliest known members of the hominin lineage, mainly early members of the genus *Homo* and still earlier species of the genus *Australopithecus*, is fraught with difficulty (for the moment, fossil samples of the very earliest identified hominins, *Sahelanthropus*, *Orrorin*, and *Ardipithecus* are much too few even to be considered here). Bones of these creatures are discovered in very different circumstances than later-in-time hominins. These early remains are usually broken and very fragmentary; multiple bones from the same individual are rarely discovered. The deposits in which they have been preserved have been formed by long-term geological processes; and they are not directly associated with archeological accumulations. The reconstruction of the taphonomic circumstances that led to the hominin bones being deposited in the geological sediments in which they were found is complex and often ends with uncertain results.

The study of general paleodemographic variables is therefore limited by the recovered skeletal and fossil samples and their contexts. These do not yield valid population samples for the construction of the sort of demographic profiles possible in the study of extant humans. Thus, the techniques of analysis and the modeling of data accumulated on these skeletal samples, even under the best of circumstances, can provide only the most preliminary and shadowy details about population structure and basic life history variables.

### 22.2 Basic parameters for paleodemographic study

#### 22.2.1 Estimation of the age at death of skeletal remains

A demographic study of a skeletal sample begins with the assessment of both the age at death and sex distribution of the skeletal material. These data are absolutely essential for the construction of other population statistics. Aging and sexing of skeletal samples of living humans has been the subject of extensive research focused on the development of techniques that can yield results with a high degree of accuracy. The problems associated with aging and sexing and the ways in which the resultant data have been modeled are discussed in a recent summary by Hoppa and Vaupel (2002).

When the sample is of nonmodern skeletal materials (Neandertals or australopithecines, for example), the criteria for judging these factors are far from certain. Establishing the age at death of a skeleton relies on knowledge of the life history of the species concerned and the biological pathways within which these hominins grew and matured. There remains uncertainty and debate about the
timing of maturational events in the dentition or the skeleton and about whether models based on living humans or chimpanzees provide greater accuracy. Recent considerations of the variation in growth that characterizes chimpanzees and living humans adds a further complication to these estimations (Zihlman et al. 2004; Monge and Mann 2006).

Although they are often considered together as part of a single aspect of paleodemography, it is our contention that potential life variables, including life span (often referred to as the study of life history), should be dealt with separately from a consideration of the achievement of this life potential (which is often viewed as a central focus of paleodemographic studies). Potential life span is an evolutionary biological phenomenon (with important implications for the evolution of culture) whereas achievement of that life potential represents the complex interaction of biology and culture. Carey and Judge (2001) aptly summarized this dichotomy when they observed that modern humans probably achieve a level of life potential far earlier than this potential can be routinely achieved. Through biomedicine, diet, sanitation, insect control, and other cultural appliances, modern societies have been attempting to reconcile these two elements: to make life potential and individual life span the same phenomenon, not just for a favored few but for all humans. In reality, while all living human populations have the potential for the same potential life expectancy, most people do not achieve this. Comparisons of differences between populations are one way to analyze the contributions and adequacy of cultural mechanisms to achieve this potential and are of possible use in paleodemography. For example, using a sample of 768 dental individuals spanning the course of most of human evolution, Caspari and Lee (2004) have argued that increased cultural complexity was primarily responsible for the increases in life span during the course of the latter phases of human evolution.

When and under what circumstances members of the human lineage achieved a modern humanlike potential life expectancy is a matter of some debate. This includes debates on all phases of life history, from infancy through childhood and adolescence to adulthood. More fundamentally, even statements that the potential of life expectancy in humans is double of that in chimpanzees must now be questioned, especially the statement that potential life span in humans is double that of chimpanzees. Maximum age for humans is frequently quoted as 90–100 years and 50 years in chimps (Sacher 1975; Hawkes et al. 1998; Bogin 1999). However, our knowledge of the life spans of chimpanzees is presently limited to a few known-age captive animals and is hampered by the paucity of field observations of wild chimpanzees, even though some have been observed for 40–50 years. Cheeta, the chimpanzee who was featured in the *Tarzan* movies, is still alive (early 2005) and healthy at 71 years of age.
The chimpanzees of Mahale have been studied for 34 years and are now providing a limited demographic data set, which suggests that death among older animals occurs between 31 and 48 years (Nishida et al. 2003). This is not radically different from the profiles of average age at death in many pre-1900 human populations and for what has been estimated for most of human history (Gage 2000; but see also Ascadi and Nemeskeri 1970). The Mahale chimpanzee study also reports that approximately 25% of older females had a postreproductive life span. This phenomenon, the equivalent of postmenopausal human females, has traditionally been cited as a uniquely human life history event. From these observational data, it is clear that this postreproductive phenomenon can no longer be considered a unique event in human life history; theories that have been associated with this pattern, e.g., the grandmother hypothesis, must be reconsidered in light of this data (Hawkes et al. 1998; Packer et al. 1998; Blurton Jones et al. 1999; Alvarez 2000; Hawkes 2003; see also Mithen Volume 3 Chapter 23), although it is possible that the extent of these postreproductive years might be greater in humans (Blurton Jones et al. 2002).

Since the process of aging causes an exponential increase in virtually all pathologies (Harrison and Roderick 1997), evolutionary selection for increased longevity must target the genes responsible for aging and not focus exclusively on a reduction in fatalities associated with pathological conditions. In baboons, longevity has a reasonably strong genetic component (Martin et al. 2002) and it is possible that chimpanzees and humans have the same potential for longevity; via cultural mechanisms, humans have reduced the cumulative effect of pathological conditions directly associated with aging. Vaupel et al. (1998) have provided a more detailed discussion of the effect of increases in longevity on human demography.

The causes of death in past populations are also difficult to determine. Nishida et al. (2003) have calculated that in the Mahale chimpanzees, just under half of deaths are caused by disease. This appears to exclude general causes associated with death by senescence. In a study of a population of chimpanzees in Bissou Guinea, Sugiyama (2004b) reported that under conditions of ecological stress, in this case deforestation, specific subsets of the group were more likely to die: infants (0–3 years of age), juveniles (4–7 years), and active adolescents (8–11 years).

The primary cause of death reported for the Hadza, a gatherer/hunter group in Tanzania, between the years 1985 and 1997 (Blurton Jones et al. 2002), appears to be disease, here also excluding death associated with the state of just being old. Sugiyama (2004a) has reported on the extent of injury in a forager-horticultural group, the Shiwiar (Ecuador). The results of 678 injuries suffered by 40 individuals indicates that trauma is likely, in fact, common at all stages of life and that
without group provisioning, the effects of these injuries would range from debilitating to lethal. If the same sorts of patterns existed in the past, it is reasonable to suggest that provisioning may have played a role in the social system of earlier hominin taxa. Berger and Trinkaus (1995) reported on the incidence and anatomical position of bone fractures in Neandertals. The position and frequency indicated that the Neandertals were living a challenging life style with a preponderance of injuries on the upper part of the body. The Krapina Neandertal collection also shows a significant number of nonlethal injuries (Kricun et al. 1999), some of which appear to have demanded provisioning of some sort, for example, the Krapina 34.7 parietal in which a large cranial depression shows a considerable amount of posttrauma healing (Mann, in preparation).

Except for the widespread signs of bacterial infection on the Middle Pleistocene Kabwe specimen from Zambia, virtually nothing is known about the cause of death in fossil hominins. Almost nothing is known about the cause of death in most recent human archeological samples as well (see, for example, a description of paleopathology in Lovell 2000). Pettitt (2000) argued, using the oldest aged Neandertal skeletons, primarily Shanidar I and La Ferrassie 1, that life was difficult in the past and that death primarily resulted from repeated sustained trauma. He based this conclusion on the general robusticity of the Neandertal skeleton, including dense bones and strong muscle markings which suggested that the body was repeatedly challenged in life. In contrast, X-ray analysis of the entire fossil skeletal sample from the site of Krapina (Kricun et al. 1999) concluded that the skeletons are of healthy individuals, with the dense bone structure indicative of an active lifestyle.

On the basis of assemblages of bones showing a lack of representation of very young and old-aged individuals, Bocquet-Appel and Arsuaga (1999) have argued that at the two largest hominin fossil sites in Europe, Krapina and Atapuerca (SH), the hominin accumulations were the result of a catastrophe. Cannibalism has been considered a possible cause for the accumulation at Krapina (White 2000); that at Atapuerca (SH) has been attributed to trapping of hominins by bears (but see also Bermudez de Castro and Nicolas 1997). The age distribution at these sites, with an overabundance of adolescents and young adults, fits the paleodemographic profile of skeletal materials caught in a catastrophic event (Paine 2000). The death profile of many catastrophes, for example, the tsunami in the Indian Ocean in early 2005, often illustrates the overwhelming overabundance of children including adolescents in the death assemblage; estimates calculate that at least one-third of the deaths in South East Asia were of children.

Carnivore activity is considered a possibly significant contributor to the australopithecine fossil assemblages in the South African dolomite caves (Brain 1981). In this instance, the preponderance of young (but not infant) individuals
might be most reasonably explained by differential predation of the young, something that is documented for African ground dwelling baboons (Mann 1975). Some sort of catastrophic event may apply to the proposed simultaneous death assemblage in the A.L. 333 site at Hadar, Ethiopia.

In a series of papers, Bocquet-Appel (1982, 1985, 1986, 1996) has emphasized the difficulties of achieving dependable paleodemographic parameters from the aging of skeletons. He has argued that no matter how they are modeled, the population profiles can only incompletely represent the living group from which they derived and only in one small slice in time. Further, considering the small, nonrandom sample sizes that are the usual subject of study, if the population from which the skeletons derive are in the process of demographic change, for example, in a general or even brief trend of population increase, then the resulting death assemblage is likely to show a preponderance of young individuals relative to the number of adults. The same pattern can also be explained by a general increase in population in-migration. Thus, without large samples sizes covering a longer time period, it would appear inappropriate to propose any broad generalizations.

Because of the nature of the fossil record, the bulk of efforts at aging concentrate on the dentition, the most likely element to preserve, although other parts of skeletal anatomy have also been used to age fossil skeletal elements.

In forensic anthropology, the determination of as precise an age at death as possible is crucial for individual identification. In paleodemography, this level of accuracy is not required and the use of life table modeling is considered to be effective. Nevertheless, derived age structure must be used to model the population appropriately in the first place, with the assumption that age-at-death differences in populations form an inherently interesting question. In human evolutionary studies, the age at death distribution question is an interesting one since it allows us to attempt to understand evolutionary process from the perspective of mortality.

One of the major critiques of paleodemography discussed by Bocquet-Appel and Masset (1982, 1985, 1986, 1996) involved the assumptions made in the process of aging a skeleton. This initiated a debate evaluating the criteria employed in the estimation of the age at death of skeletal samples (Bocquet-Appel and Masset 1982, 1985, 1996; Van Gerven and Armelagos 1983; Bocquet-Appel 1986; Greene et al. 1986; Konigsberg and Frankenberg 1994). The discussions focused on the use of aging standards based on the biases already present in the reference samples to such an extent that the resulting aging profiles mimicked the age distribution of the reference sample. Bocquet-Appel and Masset’s (1982) principal concerns about the limitations of paleodemographic studies include the assumptions that the populations from which the skeletons derived were stable,
life history patterns were the same throughout human evolution, and mortality patterns in the past can be understood using recent human and primate populations. Many of these same points were made by Howell (1982) on a paleodemographic study of the Native American Libben Site, Ohio (Lovejoy et al. 1977). A recent review by Milner et al. (2000) evaluates the issues first raised by Bocquet-Appel and Masset (1982).

These discussions require critical appraisal of the published literature on the estimation of the age at death of the skeleton (for comprehensive reviews, see Katzenberg and Saunders 2000; White 2000; Hoppa and Vaupel 2002). In many cases, these standards have been developed in the USA on the Hamann-Todd Osteological Collection (curated at the Cleveland Museum of Natural History, 1 Wade Oval Drive, Cleveland, Ohio 44106) and the Terry Collection (curated at the Department of Anthropology, Smithsonian Institution, Museum of Natural History, Washington DC 20013), reference collections of known age and sex at death individuals.

Early research that presented models of the life span of fossil hominins, summarized by Ascadi and Nemeskeri (1970), examined a variety of fossil hominin materials from Europe and Asia. Later, more elaborate discussions (Mann 1968, 1975; McKinley 1971) focused on the large fossil collection of *Australopithecus robustus* from the Swartkrans site in South Africa. On the basis of observed similarities in the pattern of dental development among the significant sample of immature individuals in the Swartkrans fossil collection to that established for modern humans, Mann argued that these early hominins matured in the prolonged period then thought to be unique to *Homo sapiens*. This conclusion was criticized by Sacher (1975, 1978), whose research on the correlation between brain size and longevity suggested that the life history trajectory of the small brained robust australopithecines was more apelike than humanlike. Smith (1989) expanded on this work, arguing for a strong correlation between dental development and brain size. More recent data on primate biology has made some of Smith's conclusions untenable. For example, factoring in variations in diet, Godfrey et al. (2001) have shown that cranial capacity alone is an insufficient predictor of dental development within primate taxa. Although not frequently quoted in anthropological reviews of life history, Carey and Judge (2001), using a large longevity sample, have shown that brain size is only one of a number of central aspects of life history. Gage (1998) has also pointed out that in order to extrapolate to primate life history, more information is needed on patterns of variation, especially environmentally induced variation. Finally, in this context, Leigh (2004) has shown that in primates, brain growth is an extremely complicated phenomenon and that adult brain size alone is not well associated with dental maturation or with the length of the juvenile growth period.
Age profiles of more recent fossil hominin accumulations are not very different from those of living peoples. Take for example, the skeletal series of Natufians (the pre- or incipient agricultural groups of the Levant) analyzed by Karasik et al. (2000). In this study, using a traditional comparative series as the standard, the mean age at death was 31.5; in contrast, applying aging standards derived from local Sinai Bedouins produced a mean age at death of 36.5. Very few individuals were placed in the older adult category of 45–50 years of age. Unfortunately, the fossil record of earlier phases of human evolution, with fragmentary, incomplete bones of few individuals generally deriving from many generations cannot be subjected to this sort of critical comparative study.

Probably the best studied fossil assemblages for which paleodemographic profiles have been developed are from Krapina and Atapuerca (SH). Each site contains a large number of individuals; for Krapina, between 75 and 92 (Wolpoff 1999) and at Atapuerca, a minimum of 32 individuals (Bermudez de Castro and Nicolas 1997). As mentioned previously, both sites have been interpreted as possessing assemblages indicative of a catastrophic event. This idea for the accumulation of the sample at Krapina was supported by White (2000) and Trinkaus (1985) but criticized by Russell (1987a, b). At Atapuerca, Bermudez de Castro and Nicolas (1997) have argued against the possible catastrophic event proposed by Bocquet-Appel and Arsuaga (1999). Age estimations based on tooth development and emergence and occlusal wear, the elements usually examined in deriving age at death determinations in fossil hominins, resulted in a relatively low average age at death at both sites. Profiles from both Atapuerca and Krapina reveal an age at death distribution with high adolescent and young adult mortality and a dearth of older individuals. In an extensive examination of Neandertal paleodemography, using 206 European and Middle Eastern Neandertal remains and comparisons to 11 modern human populations including gathering and hunting peoples, agricultural peoples, and archeological collections, Trinkaus (1995) concluded that Neandertal populations were under extensive environmental stress that resulted in a unique population profile. The elements of this profile included high levels of infant mortality extending into young adulthood, with few or no individuals surviving into older age categories (+40 years). This latter feature of the Neandertal mortality profile is unique among all the modern human populations used in his analysis, including archeological samples. Trinkaus (1995) considers other explanations for this mortality pattern and attempts to minimize the effect of the Krapina and Vindija samples on the resultant profile. These two Croatian sites account for the bulk of adolescent specimens in the overall Neandertal sample, emphasizing the possibility of alternative explanations for the unusual mortality profiles represented at these sites.
If the Middle Pleistocene Atapuerca (SH) site and the Late Pleistocene analyses by Trinkaus (1995) for Neandertals are acceptable, using life tables from modern human populations it would not appear possible for these extinct hominins to replace their numbers in each subsequent generation. In another study, Trinkaus and Thompson (1987) concluded that there were no older individuals in Neandertal populations. This leaves us in the perplexing situation of having to explain why, if these death assemblages are representative of living populations, these hominins did not become extinct after just a few generations. Clearly something is wrong with these analyses. In this context, Ogilvie et al. (1989) concluded that dental enamel hypoplasia indicates that Neandertals sustained continuing stress from weaning to adulthood, resulting from an inadequacy of foraging technique. One major problem with this analysis is the “osteological paradox” (Wood et al. 1994) in which high frequencies of stress indicators on the skeleton are actually an indication of the adequacy of cultural and/or biological mechanisms in the individuals and populations at risk, to buffer the negative environmental effects.

For Middle and Upper Pleistocene hominin samples, such as those from Atapuerca (SH) and the European Neandertals, it might be possible to use life history parameters that have been described for modern humans (but see Dean et al. 1986; Bermudez de Castro and Rosas 2001; Ramirez-Rossi and Bermudez de Castro 2004). For earlier hominins, the issue is very controversial. Caspari and Lee (2004) attempted to circumvent the problems associated with life history differences in human evolution by using dental attributes to grossly divide the hominin fossil record (including members of Australopithecus) into younger and older age categories, pointing out that this division will reasonably apply to all the taxa, regardless of possible differences in growth and development.

22.2.2 Determining the sex of skeletal materials

There are also significant limitations in the identification of the sex of a skeleton. How applicable to extinct hominins are the anatomical criteria developed on modern human samples for determining the sex of individual specimens? In general, the sex determination of earlier hominins is based on the anatomy of the ox coxae and on comparisons of the level of robusticity of the preserved postcranial bones in the sample. In the case of pelvic bones, unambiguous identification is often impossible, even when the bones are relatively complete and undistorted (Rosenberg 1988). Gracilization related to evolutionary change in fossil samples over time can confound the recognition of sex differences based
on skeletal robusticity. For example, the locus H mandible from the Lower Cave, Zhoukoudian, has been identified as a female in comparison with other mandibular specimens. However, it is possible that this Locus was deposited later in time than the other fossil bearing loci, and the more gracile nature of this fossil may be indicative of a male from a later time (Mann 1981).

The clear implication of these problems is that the recognition of sexual dimorphism within an extinct hominin species can be very difficult. Plavcan and Cope (2001) have attempted to determine the validity of species in the fossil record using metric criteria and sample variation. Other researchers have also examined this problem (Lockwood et al. 1996, 2000; Rehg and Leigh 1999), and much of this literature has recently been reviewed by Scott and Lockwood (2004). More broadly, Plavcan (2001) has reviewed the pattern of sexual dimorphism in primates. These studies consider the evidence for the presence of a range of variation that can be reasonably accommodated within a valid species; within such metrically defined species, sex differences are established along the continuum. Ultimately, however, since sample sizes of earlier hominins are very small, both sexes are often collapsed into one. As a consequence of this, the determination of sex in hominin fossil paleodemography has attracted less attention than the establishment of criteria associated with aging.

However, the identification of the sex of fossil skeletal materials can yield significant data on population structure. This is because knowledge of female mortality is crucial to understanding patterns of fertility. Using comparative data from chimpanzees and modern humans groups, Lovejoy (1981) hypothesized a demographic transition at the origin of the hominin lineage, primarily based on decreasing birth intervals. Dall and Boyd (2004) have suggested that lactation in mammals probably evolved as a way to minimize the impact of fluctuations in food resources. Thus a decrease in time spent in lactation and its subsequent effect on birth interval may have been associated with a relatively more consistent food supply in human evolution. Birth interval, age at menarche, and age at first birth (first parity) are highly variable in both chimpanzees and humans (Eveleth and Tanner 1990). Sugiyama (2004b) summarized data on chimpanzees which showed that captive animals display reduced times in each of those categories associated with fertility; in contrast, fertility patterns among wild chimpanzees are quite varied.

Although sexing the skeleton is relatively easy in strongly dimorphic species, the process in modern human populations is much more difficult. Populations and species have varied degrees of dimorphism, and it can be expressed in different ways. White (2000), in a summary of the techniques used to sex the skeleton in recent archeological populations, recommends seriating the specimens and then determining the most appropriate features within that population to use

In earlier, nonmodern hominins, the presence and extent of dimorphism is difficult to understand and quantify. Frayer and Wolpoff (1985) described various models for the identification and comprehension of sexual dimorphism in human evolution. More recent research has generated new models for understanding the context of dimorphism across the hominin lineage and among vertebrates in general. For example, if late secondary sex characteristics are primarily influenced by the production of testosterone, then an understanding of reduced dimorphism in hominins might be explained by a selection model directed toward a decrease in testosterone production or changes in its target cells. Thus, the immune suppression effect of testosterone production is reduced, influencing longevity and the role of fathers in care giving might have increased as male–male competition based on testosterone levels was reduced (Wingfield et al. 1997). This is a plausible explanation for reduction of sexual dimorphism and provides an explanation for the evolutionary role of monogamy in human evolution.

In general, however, the study of the regulation and evolution of sexually dimorphic characteristics from a physiological and genetic perspective is just beginning. It is reasonable to infer that some combination of hormonal and genetic factors plays an important role. For example, Skuse (1999) proposed a mechanism of genomic imprinting of the X chromosome as a possible mechanism, and Haqq and Donahoe (1998) reviewed the literature on individuals diagnosed with sexual ambiguity to construct a more holistic model of the factors contributing to the attribution of sex. Significant differences exist in the brains of human males and females, and sex differences are present in many biological systems (Maguire et al. 1999; Goldstein et al. 2001; Allen et al. 2003; Dubb et al. 2003; Raz et al. 2004; Shah et al. 2004; Vawter et al. 2004). Bolnick and Doebeli (2003) proposed a possible role of sexual selection and sexual dimorphism under conditions of ecological destabilization. The multiple outcomes of this theoretical model seem to indicate that there is a conflict between speciation and dimorphism, i.e., sexual selection for increased dimorphism reduces the possibility of speciation. In this model, under conditions of changing ecological landscapes during the course of human evolution, some species undergo an adaptive speciation while others evolve alternatives to speciation, including an increase in sexual dimorphism. This may be a useful explanatory factor in the differing levels of sexual dimorphism observed in hominin taxa.
For the most part, although sexing is critical to almost all types of skeletal analysis, our ability to apply this to extinct members of the hominin lineage is difficult. Since the number of skeletons present in any analysis of the life history or paleodemography of fossil hominin samples is so small, it makes sense to pool both the male and female skeletons and consider them as a single sample.

Among the confounding difficulties which have led to the pooling of samples is the inability to distinguish dimorphic characteristics among the earliest hominins (including *Australopithecus*). Numerous arguments focused on the evolution of sex differences in the pelvis and in other features related to dimorphism (i.e., female vs. male stature). Assuming the obstetrical dilemma in human evolution, and without knowledge as to the exact time frame when this would have occurred in human biological history, research has pointed to possible evolutionary mechanisms responsible for these differences including sexual selection for more fecund female mates. Guegan et al. (2000) presented data on populations in 38 countries to show that stature dimorphism in females in modern populations could be correlated with complications associated with pregnancy and the birthing process. Nettle (2002) has shown that female height is correlated with reproductive success but that maximum success occurred in females who were below the mean for height. Integrating the data from both these studies suggests that over time female height may be more conservative than male height. Thus, differences in dimorphism in human evolution may be related in large measure to variations in males, with female biology remaining somewhat stable. Studies of living humans appear to show that females are less vulnerable to environmental influences on growth processes than males (Stini 1985).

Sexual selection has also been implicated in the evolution of body dimorphism. For example, Pawlowski and Grabarczyk (2003) have argued that the low center of gravity in females, manifest after puberty and adaptive for both pregnancy and the carrying of infants, is the result of sexual selection by males for this specific female body form.

The *os coxa* is the single most dimorphic feature of humans and, according to Tague and Lovejoy (1986), probably has been for at least the last few million years. The anatomy of the known sample of hominin pelvic bones appears to be related to the conflicting needs of both efficient bipedality and the problems associated with birthing relatively large-brained babies with broad shoulders. It appears that some of the dimorphism present in adult pelvises might actually be present *in utero* (Holcomb and Konigsberg 1995). In addition, it is possible that race affects the expression of sexual dimorphism in the pelvis (Patriquin et al. 2003). In modern populations, the accuracy of the assignation of sex using the pelvis is close to 95% (Murai et al. 1999; Bruzek 2002). According to Leutenegger (1982), all primate females possess a greater ischiopubic index than males do.
Although biases exist in the determination of sex based on features of the skull, there appear to be differential differences between the preservation of female versus male skeletons (Walker et al. 1988). There is a tendency to identify older female skulls as male. This is no doubt a direct consequence that the skull becomes more “masculine” as it ages (Meindl et al. 1985); it is difficult, however, to know if this bias applies to fossil hominin studies. Susanne et al. (1985) present data on age changes in cephalic dimensions.

The distinctive features of the male and female os coxae are universal in living humans (and probably most extinct species as well), although there might be some variation in the degree of expression of the differences within these populations. The same, however, does not apply to other characteristics used in sexing the skeleton. Thus, in concert with the techniques applied to determining the age at death of a skeleton, sexing techniques must be population specific. This can be accomplished either through analysis based on the data accumulated on a reference sample of known sex (Steyn and Iscan 1997; Graw et al. 1999; Mall et al. 2000; Asala 2001; Schiwy-Bochat 2001; Pettenati-Soubayroux et al. 2002; Bidmos and Asala 2004) or through seriation of a group of unknown specimens (White 2000) and the application of a variety of statistical techniques to the data. Safont et al. (2000) have employed this method on a modern human sample. Since it can generally be assumed that an unknown sample contains both male and female skeletons, it is reasonable to sort the skeletal elements into male and female categories.

In fossil hominin studies, in contrast, because it is not possible to derive a set of metric or nonmetric characteristics associated with sex (or age for that matter) on an applicable reference sample, it is necessary to derive a set a parameters that best describes (statistically or with other methods) the variation in the sample being examined. Depending on its place in the hominin timescale, comparisons can be made to hominoids, especially chimpanzees, or to living human populations.

An example of this type of analysis was that of Reno et al. (2003) on a fossil sample from Afar Locality A.L. 333 and assigned to A. afarensis (see also the commentary by Larson 2003). Since the A.L. 333 locale is considered on geological grounds to be a simultaneous death assemblage, it was assumed that the fossil sample represented males and females of the same species. Simulations were undertaken to compare the Afar fossils to modern humans, chimpanzees, and gorillas. Using measurements of postcranial elements, A. afarensis was found to be closest to H. sapiens in degree of sexual dimorphism (with H. sapiens intermediate between the monomorphism of chimps and extreme dimorphism in Gorilla in postcranial dimensions). These researchers also question the simple extrapolation of dimorphism to social categories in primates. They emphasized the striking
dissimilarity in sexual dimorphism between canine tooth maturation in chimpanzees in conjunction with their almost negligible postcranial dimorphism. They conclude that *A. afarensis* possessed a very distinct pattern from polygamous chimpanzees. In this analysis, monogamy is probably the most likely pattern of social organization among these early fossil hominins. Richmond and Jungers (1995) and Lockwood et al. (1996, 2000) have also investigated the pattern of sexual dimorphism in *A. afarensis*. Examinations of sexual dimorphism have been performed on *A. boisei* specimens (Silverman et al. 2001), face dimorphism in *A. africanus* (Lockwood 1999), sexual dimorphism in *Paranthropus robustus* and early *Homo* (Susman et al. 2001), and the mandibular metrics of a comparative sample of *H. sapiens, Pan troglodytes, Pongo pygmaeus pygmaeus*, and *Gorilla gorilla gorilla* (Humphrey et al. 1999).

One of the most extensive investigations of sex assignation in a specific sample was undertaken by Bermudez de Castro and Nicolas (1997) on the fossil materials from the Spanish site of Atapuerca (SH). A total sample of 32 individuals were examined, with a 1:1 sex ratio derived from the specimens that could be sexed. They report an overrepresentation of females in the age category between 16 and 20 years. This may be a reflection of a high female mortality in early child bearing years. Additional studies on this collection have been done by Rosas et al. (2002) and Bermudez de Castro et al. (2001), who examined the level of sexual dimorphism in the sample as revealed in mandibular and dental measurements, respectively. Bermudez de Castro et al. (2001) concluded that the dentition showed greater sexual dimorphism than that found in modern humans. In the mandible, sexual dimorphic patterns were present but differed from those in modern humans. Arsuaga et al. (1997) looked at body size and cranial capacity dimorphism, reporting a degree of dimorphism similar to other Middle Pleistocene hominins and modern humans.

Wolpoff (1999) noted that sexual dimorphic characteristics, including overall cranial size and capacity, vault thickness, superstructures and toruses (mastoid process, sagittal keel, nuchal torus), forehead curvature, and functionally related features of facial size and robustness, vary in expression in recent human geographic populations and are a reflection of the hominin evolutionary past in each region. On the basis of these observations, Wolpoff (1999) identified male and female sex differences in an extensive sample of Middle and Upper Pleistocene hominins. Weidenreich’s (1935, 1943) detailed studies of the morphology of the *H. erectus* sample from Zhoukoudian suggested a relatively low level of sexual dimorphism, a conclusion that was also found by Mann (1981), who studied the virtually complete Zhoukoudian cast collection.

Other studies of the application of techniques of sexing to fossil hominin materials include the work of Coqueugniot et al. (2000) as well as the application
of mandibular ramus posterior flexure to a sample of Neandertals and early modern humans (Loth and Henneberg 1996); dimorphism in chin morphology in the specimens from Klasies River Mouth (Lam et al. 1996); an analysis of the Kebara 2 pelvis using various bony dimensions (Tague 1992). Finally, Trinkaus (1980) employed indices of robusticity of postcranial elements to show that European and Near Eastern Neandertal limb bones show the same degree of sexual dimorphism as modern humans in this feature.

22.3 Other paleodemographic parameters

22.3.1 Life history

Life history variables, including brain and body size, neonatal weight, length of gestation, life span, age of sexual maturation, age of weaning, are all correlated to each other; various theories have been proposed to explain the evolutionary mechanisms through which this occurs. Using data on living primates, Harvey and Clutton-Brock (1985) noted that the distinctive features of this mammalian order are large brains, prolonged maturation, and long life spans. Understanding the relationships of these variables to each other from an evolutionary perspective has been the subject of numerous projects. Pereira (1993) has summarized this work, including a discussion of allometric or correlation analysis. Heterochrony has also been used to explain life history developmental processes that may have characterized human evolution (Gould 1977; Minugh-Purvis and McNamara 2002). The usefulness of heterochrony has been critically evaluated by Godfrey and Sutherland (1996) and Shea (1989).

Gage (1998) compiled all known mortality and fertility data on a broad group of primates. He concluded that a comparison of human and chimpanzees life histories indicates that delayed maturation is a characteristic of humans, whereas an extension of the overall time frame of reproduction, along with an increase in the calculated rate of aging, appears characteristic of chimpanzees. Chimpanzee character state of life history is evolutionarily derived and thus does not make a useful model for understanding the last common ancestor of chimpanzees and humans. Although this observation must be kept in mind, chimpanzees are our closest living relative; the use of the growing body of literature on chimpanzee studies, especially in the wild, can reasonably provide a point of comparison not only to living humans but also to extinct members of the human lineage. The human life history pattern as described by Smith and Tompkins (1995 p 260) is that “humans take about twice as long to erupt teeth, twice as long to reach adulthood, and live about twice as long as great apes.” This probably
represents an overstatement of the unique position of humans within the Primate Order. For example, the work of Zihlman et al. (2004) shows that wild chimpanzees take upward of 3 years longer to mature than animals in captivity. Using M1 eruption times as a proxy for other maturational events, chimpanzees now appear to overlap the range of modern humans. Recent work on sexual maturation of chimpanzees in the wild shows that some groups do not mature until 14 years of age (Sugiyama 2004b).

A comprehensive description of life history in mammals was analyzed using an energetics model by Hill and Kaplan (1999), and an evolutionary model of longevity increases was presented by Carey and Judge (2001). Using game theory, Brommer (2000) also discussed the evolution of life history using the evolutionary concept of fitness. Using seven anthropoid primate species, Leigh (2004) has shown that life history among the primates cannot be related solely to brain size but more specifically to the point in life history in which brain growth occurs. The correlation of diet to primate life history has been addressed by Godfrey et al. (2001) and Kaplan et al. (2000). Day et al. (2002) associated life history variables across various species of animals with the level of predator pressure. Bolnick and Doebeli (2003) have also proposed that species confronted with ecological instability adapt in a number of ways, including changes in sexual dimorphism, speciation, or an alteration of ontogenetic processes that reduces the influence of the destabilizing ecological events. It is possible that some and all combinations of these outcomes have occurred in human evolution. Of critical importance is the plausible role of ontogenetic changes as an adaptive feature in at least some species in human evolution. If, for example, A. afarensis does indeed show little sexual dimorphism and, by extrapolation from primate models, this indicates a pattern of monogamy among these hominins, then it is indeed possible that altricial young were also part of this pattern, further supporting Lovejoy’s (1981) hypothesis.

Since life history theory is built on the foundation of living animals, it becomes a challenge to integrate fossil hominin species into these analyses. It has been argued that correlations of brain and body size to life history variables supersede any possible analysis of the fossil materials and that all data must be interpreted in this context. Certainly evolutionary events have produced unique combinations of life history features in the past; and if it is possible to integrate these into the correlation studies, it might serve to more fully represent the life history of hominins across time and space. There appears to be no consensus as to when in the course of hominin evolution modern human-like life histories evolved. Various perspectives on the evolution of life history have been presented (Smith and Thompkins 1995; Tillier 1995; Bogin 1999; Minugh-Purvis and McNamara 2002; Thompson et al. 2003).
In order to reconstruct the life history patterns of earlier hominins, most research has concentrated on the examination of those biological patterns that may yield data documenting rates of maturation. Overwhelmingly, this has meant focusing on the developing dentition with the assumption that the maturation of dental hard tissues and the sequential eruption of the teeth are under strong genetic control, with a minimum of possible environmental influence. Unlike bone, which is subject to remodeling throughout life, dental enamel appears to be relatively stable, preserving the initial structures. Most research on the maturation patterns of earlier hominins focuses either on the pattern and sequential eruption of the developing dentition or on the examination of dental microstructures as time-dependent features. Comparisons between fossil hominins are most usually made to the living great apes, especially chimpanzees, and to modern humans.

### 22.3.1.1 Patterns of maturation

Chimpanzees and humans are characterized by different life history strategies; this should be apparent in the dental calcification and eruption schedules of the two species. What if any pattern differences have been described? The most prominent is that chimpanzees have an accelerated development and eruption of the M1 especially in relationship to the development of I1 (Smith 1994, 2000; critique by Mann et al. 1990). It has also been observed that chimpanzees have a time overlap in the calcification schedule of the molar sequence (Anemone 2002). And finally, chimpanzees have a significant difference in the pattern of calcification and eruption of the permanent canines. Since this tooth is so functionally and anatomically distinct from that of humans, the canine is probably not a good indicator of life history pattern differences (Lampl et al. 1993).

Various models have been used to explain these differences. These include differences in life history (see for example Smith 2000 and the critique by Lampl et al. 2000) but other explanations have been proposed (Simpson et al. 1990, Simpson and Kunos 1998).

Many scholars have undertaken general discussions of how dental development of fossil hominin samples can be understood as part of life history (Bogin 1990, 1999; Smith and Tompkins 1995; Bogin and Smith 1996; Kuykendall 2003). Discussions of life history in the early phases of human evolution have been extensively discussed (Dean 1985; Smith 1986, 1989, 1991, 1992, 1994; Conroy and Vannier 1987, 1989; Mann et al. 1987; Conroy 1988; Mann 1988; Wolpoff et al. 1988; Conroy and Kuykendall 1995; Smith and Tompkins 1995; Clegg and Aiello 1999; Dean et al. 2001; Moggi-Cecchi 2001). Many investigations have also focused on the later phases of human evolution (Dean et al. 1986; Tompkins

22.3.1.2 Dental microstructure

Some researchers have maintained that dental enamel and dentin microstructures are useful tools for the reconstruction of the timing of dental development. Dental microstructure is a hard tissue relic of the ontogenetic processes that govern tooth growth (Ramirez-Rozzi 1998a, b, 2002; Ramirez-Rozzi et al. 1999; Ramirez Rozzi and Bermudez de Castro 2004; Guatelli-Steinberg et al. 2005). Conversely, it is also possible that these structures reflect a microworld of minianatomical detail that may or may not be useful in the timing of dental development or the reconstruction of phylogenetic relationships.

Bromage and Dean (1985) presented data to support the idea that the timing of tooth development in fossil hominins could be estimated using microstructural details of enamel. Since then there has been much debate about the applicability of these hard tissues to understanding of the times of maturational events in earlier hominins (Bromage and Dean 1985; Dean 1985, 1987a–c, 1998, 1999, 2000a, b; Beynon and Dean 1987, 1988; Beynon and Wood 1987; Bromage 1987, 1989, 1990; Mann et al. 1987, 1990; Dean et al. 1993; Beynon et al. 1998; Moggi-Cecchi et al. 1998; Dean and Reid 2001; Moggi-Cecchi 2001; Ramirez Rozzi and Bermudez de Castro 2004; Guatelli-Steinberg et al. 2005).

Finally, growth and development studies have been undertaken on the femur (Tardieu 1998) and pelvis (Berge 1995) of fossil hominins. In both these studies, although a humanlike pattern of growth best describes all members of the genus Homo, australopithecine-grade hominins probably had growth trajectories similar to those in chimpanzees.

What can be concluded from this diverse body of research? Even where a virtually complete skeleton of a youngster (KNM-WT 15000) has been recovered, it has been difficult to reach a consensus about its rate of maturation and its age at death (Clegg and Aiello 1999). The diversity of research on the patterns of maturation in earlier hominins is well illustrated in the edited volume, *Patterns of Growth and Development in the Genus Homo* (Thompson et al. 2003). But it remains very difficult to compare the work presented by one researcher with that of another because the fossil samples and the techniques of analysis that are employed are so different.

However, with some reservations, the research results appear to support the general recognition that, by the appearance of members of the genus Homo, there was a maturational shift to a more modern humanlike pattern, although that pattern might be manifested in slightly different ways in individual species within...
Homo. If this cautious conclusion continues to be supported by additional data, it will justify the use of the growth and development patterns of modern humans as the reference data in paleodemographic reconstructions. What sorts of patterns characterized the maturation of the still earlier members of the hominin lineage remains uncertain. However, recent information documenting significant variation in maturational events in both modern humans and chimpanzees suggests that the traditional notion of a uniquely human prolonged period of maturation may have to be reconsidered.

22.4 Conclusions

1. The paleodemography of extinct hominin taxa has not produced a corpus of dependable data, and it remains possible that reasonable population-based demographic parameters from fossil assemblages will remain unattainable into the foreseeable future.

2. In contrast, life history reconstruction, establishing some basic parameters associated with demographic analysis, is a more achievable goal. Among these parameters are potential life expectancy, time of maturation, and age at weaning. The accumulation of additional information on living primates has made the simple association of life history variables with gross size variables (e.g., brain size and body size) increasingly untenable.

3. The larger the database on captive and wild chimpanzees, the more difficult it becomes to clearly distinguish their life history variables from those of living humans. This will certainly affect our interpretations of life history in fossil hominin species. Similarly, the more knowledge we have of the extent of modern human variation and plasticity, the more difficult it becomes to specifically categorize human life history.

4. Culture (in conjunction with significant developmental plasticity) may be more important as regard understanding human life history than biology, especially in variations in the expression of features such as longevity and age at weaning, and perhaps even maturation rates, general reduction in the age of first menstruation, and others. Such factors may better explain the large ranges of variation that have been observed in both humans and chimpanzees.

In sum, we know very little of the demography of earlier members of the hominin lineage, and much that appears to be understood requires reevaluation on the basis of newly acquired data from nonhuman primates and the increasing comprehension of the range of variation that exists in human growth and maturation.

Abstract

Many models have been developed to depict the behavior and ecology of our earliest relatives. However, the Man the Hunter model has been the most widely accepted way of viewing human evolution. This theory gained ground in the mid-twentieth century and has been recycled ever since under various guises in the scientific and popular literature. Many human traits, such as bipedalism, monogamy, territoriality, tool use, technological invention, male aggression, group-living, and sociality, are often linked to this perspective. However, while theories and associations of human aggressive hunters abound, they are rarely based on the two evidentiary approaches that shed light on early hominid ecology and behavior—living primate models and the fossil record. Here, we outline a methodology of reconstructing early human behavior by using both the fossil record and extant primate ecology and behavior. Data on early human fossils, on modern primates living in similar habitats to our earliest ancestors, and on predators both today and in the distant past indicate that Man the Hunted may be a more accurate descriptor of our earliest relatives. We describe the evidence for the Man the Hunted theory, some of the behavioral patterns that were needed to protect our earliest ancestors from predation, and how this may lead to a new perspective on certain aspects of human nature.

23.1 Introduction

In the early 1950s, Bartholomew and Birdsell (1953) published their classic paper *Ecology and the Protohominids*. This was among the first attempts to develop a method for reconstructing the behavior and ecology of our earliest hominid ancestors. They suggested that it should “be possible to extrapolate upward from ecological data on other mammals and suggest the biological attributes of the protohominids and to extrapolate downwards from ethnological data on hunting and collecting peoples and suggest the minimal cultural attributes of the protohominids” (p 481). This paper was precipitated by the realization, in the
late 1940s and early 1950s, that australopithecines were indeed our earliest ancestors and that in most ways they were more similar to nonhuman primates than to modern humans (Sussman 2000). Since then a number of models have been proposed using research on nonhuman primates to reconstruct early human ecology and behavior.

The most persistent model and one that occurs repeatedly in the literature on human evolution is the “Man the Hunter” model. Among the earliest renditions of this scenario was that developed by Dart after his fossil discoveries in South Africa. From the fragmented state of the bones and the damage on the early hominid skulls, he concluded that this species had used bone, tooth, and antler tools to kill, butcher, and eat prey, as well as to kill one another (Dart 1953). Between 1961 and 1976, Dart’s view was popularized by Robert Ardrey in a number of books, including African Genesis, The Hunting Hypothesis, and The Territorial Imperative. The evidence for Dart’s theory was not good, however. On examination of the same evidence, Brain (1981) noted that the bones associated with these early hominids were exactly like fragments left by leopards and hyenas. It seems that Dart’s australopithecines may have been the hunted and not the hunters.

In the late 1960s, Washburn and his colleagues restated the Man the Hunter theme (Washburn and Lancaster 1968). Rather than amassing an adequate amount of evidence to prove their theory, Washburn and his colleagues used the nineteenth-century concept of cultural “survivals.” Behaviors like hunting that persist from an earlier time but are no longer useful in modern society were seen as part of our inherent biology. Another major proponent of the Man the Hunter model was E.O. Wilson in the mid-1970s. He claimed that a number of human traits, such as territoriality, aggressive dominance hierarchies, male dominance over females, permanent male–female bonds, and female philopatry, are relatively constant among our primate relatives and persist throughout human evolution and in human societies, generally. Furthermore, he believed these traits provide important evidence of our hunting past (Wilson 1975).

One of the most recent models of our hunting past is that provided by Wrangham and Peterson (1996). They proposed that killing and violence against adults of their own species are traits shared by hominids and chimpanzees and that, since these traits are rare among other animals, they were inherited from our ancient common ancestor. In fact, unlike earlier models which proposed that killing developed out of our propensity for hunting, in Wrangham’s and Peterson’s model it is this violent nature and natural blood lust that makes both humans and chimpanzees such good hunters. The latter three models have been reviewed elsewhere and found to be lacking in substantive evidence (Sussman 1999a, b, 2004; Marks 2002; Hart and Sussman 2005; Fry 2006).
23.2 Reconstructing the behavior of the earliest hominids

If the evidence for Man the Hunter has not been good, what kinds of evidence should be used in attempts to reconstruct the behavior of our earliest ancestors?

The most important evidence includes careful examination and understanding of the actual skeletal remains of the creatures. Other fossil evidence, such as tools or footprints, left by our earliest relatives and fossil materials that give us clues about the environment in which they lived, such as fauna, flora, or water sources, also must be examined. These fossils provide the most important data for accurate reconstructions. Many Man the Hunter theories fall short in the critical examination of the fossil evidence (if fossils are used at all). Stanford noted this lack of fossil evidence in such evolutionary theories: “… models of hominid evolution are, appearances notwithstanding, virtually fossil-free” (Allen and Stanford 1992, Stanford personal communication).

Besides fossils, other types of secondary evidence used in reconstructions are less reliable but, nonetheless, can offer insights. We would rank these in the following order as far as applicability to reconstructing early hominid lifestyles: (1) the behavior of nonhuman primates living under similar ecological conditions to those of our early ancestors. It is best to keep timing in mind with this approach since habitats and climates change throughout our evolutionary history. (2) The behavior of our genetically closest primate relatives such as chimpanzees, bonobos, and gorillas. However, lumping all the great apes together as one analog when they are so diverse is dangerous. Although some characteristics may remain conservative within a taxonomic group, others are not shared. For example, monogamous pair bonds among the lesser apes or upright posture among the apes might be considered phylogenetically conservative traits, shared by all or most species within a taxon. (3) Characteristics shared by certain (or all) modern humans that might also be similar to our earliest ancestors. Modern foragers, however, are just as advanced and evolved within their own cultures and environments as any Western urban dwellers. Our least confident recommendation is (4) the behavior of other animal species that might be living under similar conditions or share some aspects of the lifestyle of early humans such as certain carnivore or prey species.

In using any of these types of secondary evidence, if we are not extremely careful (because in many cases similar looking behaviors are not the same), we can end up comparing apples with oranges or lions with hominids. Obviously, words with loaded meaning for humans—war, rape, murder, infanticide, and genocide to name a few—must be used with extreme caution when referring to
the activities of nonhuman species. In this regard, Marks (2002 p 104) warns against “... a science of metaphorical, not of biological, connections.”

We cannot, therefore, necessarily impute correlation between human ancestors and data based on extant carnivores, modern human foragers, or great apes. For example, even the concept of hunting in chimps and humans is quite different. Present-day human hunters purposely search for animal prey but chimpanzees do not: “Instead, they forage for plant foods and eat prey animals opportunistically in the course of looking for fruits and leaves” (Stanford 1999 p 48). Furthermore, reconstructions must always be compatible with the actual fossil data—the fossils are real but the models we construct are hypothetical and must constantly be tested and reconfirmed. Lastly, when attempting to construct models of our early ancestors’ behavior, it is necessary to be precise about timing. If we say our earliest human ancestors (those who lived 7 Ma) behaved in a certain way, we cannot use fossil evidence from 2 Ma.

As a case in point about timing, we pose the question: Could hunting have occurred without tools? The first evidence of stone tools comes from around 2.6 Ma (Semaw 2000). The earliest hominin fossils, however, date from almost 7 Ma, at least 4 Myr before the first stone tools. When we look at the fossil evidence, hunting came quite late to our human family. Interpretations of hominin behavior, therefore, should be conservative and cautious, as stated by Klein (1999 p 306): “... the mere presence of animal bones at archeological sites does not prove that hominids were killing animals or even necessarily exploiting meat. Indeed, as was the case in the earlier South African sites, the hominin remains themselves may have been the meal refuse of large carnivores.”

The transition to hunting as a dominant way of life does not appear to have started until after the appearance of our own genus, Homo, and may not have even begun with the earliest members of our genus. Homo erectus has been given credit in the past for existing as a large animal hunter, and dates as far back as 1.75 Ma have been hypothesized for such a lifestyle. But if we take a conservative approach to this subject—looking only at facts and fossils and not imaginative speculations—the first unambiguous indications of hunting may be amazingly recent (Binford 1992; Klein 1999).

No hard archeological evidence, in other words, no fossil evidence of tools designed for hunting exist earlier in time than a finely shaped wooden spear excavated at Schöningen, Germany, dated at approximately 400,000 years of age (Dennell 1997; Theime 1997). The famous Torralba and Ambrona sites in Spain, dated at 500 ka, contain huge numbers of large mammal bones and were thought to represent unquestionable evidence of megafauna killed by Pleistocene hunters. Now these two sites are being reconsidered in the light of better archeological analysis. Elephant bones at these sites could just as likely
represent natural deaths or carnivore kills as the remains of human hunting (Klein 1987, 1999).

Further, no hominids were large-scale hunters before they had the use of fire (because of their dentition and alimentary tract, points we will elucidate later), although insects, small vertebrates, lizards, and birds were likely eaten opportunistically. The best evidence for the controlled use of fire appears around 800 ka in Israel (Goren-Inbar et al. 2004). Klein (1999 p 160) states: “The assumption of consistent hunting has been challenged, especially by archeologists who argue that the evidence does not prove the hunting hypothesis . . . it is crucial to remember (although not as exciting) that probably the majority of calories [came] from gathering plant foods.”

### 23.3 Dentition and diet

Whether *H. erectus* or any other hominid hunted or scavenged before 800 ka may be a moot question. Hunting would only be an activity undertaken if early hunters could eat what they killed, and to eat meat it is necessary to have teeth capable of masticating and processing meat.

Man the Hunter models of human evolution assume that a significant portion of our earliest ancestors’ diets must have come from killing and eating meat from relatively large mammals. By comparing the characteristics of the dental and jaw morphology of various living primates with those of fossils, we can make inferences about the diets of early hominids. Teaford and Ungar (2000; Ungar 2004) carried out just such a comparison in an attempt to reconstruct the early hominid diet. Using such features as tooth size, tooth shape, enamel structure, dental microwear, jaw biomechanics, and occlusal slope and relief of the lower molars, they found that the earliest humans had a unique combination of dental characteristics and a diet different from modern apes or modern humans.

*Australopithecus afarensis* is characterized by jawbones that are thick, with relatively small incisors and canines in relation to molars. The molars, by comparison with other primates, are huge, flat and blunt, show less slope and relief, and lack the long-shearing crests necessary to mince flesh. *A. afarensis* also had larger front than back molars. The dental enamel is thick and microwear on the teeth is a mosaic of gorilla-like fine-wear striations (indicating leaf-eating) and baboon-like pits and microflakes (indicating fruits, seeds, and tubers in the diet).

When mammalian omnivore species are compared, body mass is positively correlated with inclusion of plant protein in lieu of animal protein in the diet. If insects are ingested, they are usually social ones that come in large “packages”
because it takes a higher amount of energy to capture individual insects. In studies of mid- to large-sized primates, such as macaques, baboons, chimpanzees, and modern human foragers, in which the amount of time spent obtaining animal protein has been quantified, the total is very low, usually making up less than 5% of the diet (Garber 1987; Sussman 1999c).

Given these facts, we hypothesize that early humans were able to exploit a wide range of dietary resources, including hard, brittle foods (tough fruits, nuts, seeds, and pods), as well as soft, weak foods (ripe fruits, young leaves and herbs, flowers and buds). They may also have been able to eat abrasive objects, including gritty plant parts such as grass seeds, roots, rhizomes, and underground tubers. As stated by Teaford and Ungar (2000 pp 13508–13509), “this ability to eat both hard and soft foods, plus abrasive and nonabrasive foods, would have left early hominids particularly well suited for life in a variety of habitats, ranging from gallery forest to open savanna.” Dental morphology indicates that the earliest hominids would have had difficulty breaking down tough pliant plant foods, such as soft, fibrous seed coats, and the veins and stems of mature leaves. Another tough plant food that our early ancestors would have had difficulty processing was meat. Teaford and Ungar (2000 p 13509) stress that “the early hominids were not dentally preadapted to eat meat — they simply did not have the sharp, reciprocally concave shearing blades necessary to retain and cut such foods.”

Both modern chimpanzees and humans have an alimentary track that is neither specialized for eating leaves nor animal protein: instead, it is more generalized, similar to the majority of primates who are omnivorous and eat a mixture of food types (Chivers and Hladik 1980; Martin et al. 1985; Martin 1990). Furthermore, at least two-thirds of modern-day foragers’ food comes from women gathering plant foods and, in the process, opportunistically capturing small mammals and reptiles. Less than one-third of the diet (the meat portion brought in by dedicated male hunters) serves to supplement their foraged nutritional intake, except in cold climates or where fishing is prevalent (Marlowe 2005).

Modern dietary concerns in industrial societies revolve around the amounts of both fat and red meat consumed by the average person. The medical community warns that meat should be ingested in limited quantities. “Diseases of affluence” caused by high-protein, high-fat diets include raised cholesterol levels, high blood pressure, heart disease, stroke, breast cancer, colon cancer, and diabetes—all correlated to a diet exorbitantly rich in red meat. With colon cancer, in particular, startling data are available: Daily red-meat eaters are two and one-half times more likely to develop this cancer than people adhering to a mostly vegetarian diet (Willett et al. 1990). In a study in which Chinese rural villagers (eating a traditional diet low in meat) were compared to their urban counterparts
(who ate more meat), it was found that individuals following a low-fat, low-meat diet suffered less anemia and osteoporosis (conditions commonly associated with food low in animal products) than individuals higher on the meat-consuming ladder (Chen et al. 1990; Campbell and Campbell 2005). Campbell states: “We’re basically a vegetarian species and should be eating a wide variety of plant foods and minimizing our intake of animal foods” (Brody 1990 p C2).

No hominids could have hunted for a meat diet on a large scale before the advent of controlled fire. We did not have the dentition or the digestive tract of a carnivore. The anatomy and physiology of early hominids did not particularly suit them for digesting meat until the mastery of cooking. The human intestinal tract is short and predigestion of meat by fire had to precede any major meat eating, although we still require certain nutrients that are not obtainable from a meat diet. As stated earlier, the oldest known hearths with good evidence for controlled use of fire are dated at approximately 800,000 years.

### 23.4 Locomotion

By far the best known of early australopithecine species is *A. afarensis*, with many fossil remains dating from 3.6 to 2.9 Ma and possibly as far back as 5 Ma. Collections from Hadar, Ethiopia alone have yielded 250 specimens, representing at least 35 individuals, and there are a number of other East African digs that contain remains of this species. Specimens include Lucy (dated at 3.2 Ma), the most complete adult skeleton from this time period, and fossil footprints from Laetoli, Tanzania ash deposits (dated at 3.6 Ma). Furthermore, most hypotheses concerning human evolution position *A. afarensis* as a pivotal species from which all other later hominids, including *Homo*, evolved (Fleagle 1999; Conroy 2005).

Given the previous facts, we see *A. afarensis* as a good species to examine when attempting to reconstruct the appearance and behavior of one of our early human ancestors.

Terrestrial bipedalism is a hallmark of the whole fossil hominid family. This mode of locomotion can be inferred from fossil specimens nearly 7-Myr old (Galik et al. 2004). It appears long before the vast growth of open grasslands in Africa and before the expansion of human brain size and recognizable stone tool making. Besides fossilized bones, direct evidence of early bipedalism comes from the Laetoli footprints where two hominids were walking together in soft ash almost 4 Ma (White 1980; Day 1985; Tuttle 1985; Klein 1999). However, looking at the skeletal evidence, the locomotion of these early hominids was not exactly identical to ours. In fact, *A. afarensis* seems to have been a primate equally at home in the trees or on the ground.
This is indicated by a number of factors. First, the limb proportions are different from modern humans. The arms are similar in proportion to modern humans, but the legs are relatively shorter—more apelike—which implies the use of suspensory locomotion in the trees (Kimbel et al. 1994). Other aspects of the upper limbs also retain a number of features indicating an ability to move easily in the trees. The wrist and hand bones are quite chimpanzee-like; the finger and toe bones are slender and curved as in apes, giving *A. afarensis* grasping capabilities compatible with suspensory behaviors. The toe bones are relatively longer and more curved than in *H. sapiens*, the joints of the hands and feet, and the overall proportions of the foot bones all reinforce evidence for climbing adaptations and arboreal activity. Nevertheless, the relative thumb length of these hominids is closer to that of modern humans than it is to chimpanzees (Susman et al. 1984; Smith 1995; Corkern 1997; Alba et al. 2003; Conroy 2005).

The pelvis and lower limbs of *A. afarensis* are a mixture of humanlike and apelike features. These anatomical components and the shorter leg length indicate that *A. afarensis* may have used less energy while walking, whereas transition speeds from walking to running may have been lower with slower running speeds than modern longer legged humans (Steudel-Numbers 2003). Overall, Rak (1991 p 283) summarizes: “Although clearly bipedal and highly terrestrial, Lucy evidently achieved this mode of locomotion through a solution of her own.”

Does this mixture of anatomical features indicate anything about the efficiency of early hominid locomotion? It was once thought that the Neotropical marmosets and tamarins were restricted in their ability to move on small branches because they have claws instead of the standard primate nails on their hands and feet. However, claws do not restrict callitrichid locomotion on thin branches; their claws also enable them to utilize large trunks much like squirrels do. Claws allow them to be more versatile, and they can use a wider range of arboreal habitats than most other New World monkeys (Garber 1984; Sussman and Kinzey 1984). It appears that the combination of skeletal characteristics found in *A. afarensis* enabled this hominid to be versatile in a similar way. They were able to use the ground and the trees equally and successfully for a very long time. We believe these early hominids were well-adapted to their environment and not in the least inhibited by switching back and forth from bipedalism on the ground to quadrupedalism in the trees.

There are at least seven different “models” that have been proposed to account for bipedalism as a hominid adaptive strategy: the *tool using and making* model (Darwin 1874; Washburn 1960; Sinclair et al. 1986), the *carrying* model (Hewes 1961, 1964; Lovejoy 1981), the *vigilance* model (Dart and Craig 1959; Day 1986), the *heat dissipation* model (Wheeler 1984, 1991), the *energy efficiency*
model (Rodman and McHenry 1980; Steudel 1994), the display model (Jablonski and Chaplin 1993), and the foraging model (Hunt 1994). However, there are many primates who spend most of their time on the ground and none of these developed bipedalism, even though each of the theorized advantages presumably also would have accrued to them.

It is difficult to separate consequence from causation. None of the theories may be causative; instead, all the theoretical causes may be results of a primate preadaptation to being bipedal. All the great apes are preadapted to bipedality. When our ancestors came down from the trees, bipedalism was possible because of body proportions and suspensory adaptations—longer arms and shorter legs that allow gibbons, orangutans, and chimpanzees to hang from trees and forage for fruit. All apes have varying capacities for erect posture and are able to walk upright for short periods of time; bonobos, especially, will stride upright with humanlike posture. However, we propose that when the earliest hominids began using the ground for a major portion of their activities, their body proportions were more suited for bipedalism than other forms of locomotion, i.e., quadrupedalism or knuckle-walking.

Although it is important to see early hominids in the context of hominid evolution, it is equally important to realize that in the same way that they were not little people, they also were not just bipedal chimps, but the beginning of a new radiation of very different hominoids. It is this uniqueness that makes reconstructing hominid origins so difficult. Thus although early hominids and their bipedal adaptations are certainly derived from an African apelike ancestry, human bipedalism is morphologically and physiologically different from the occasional facultative bipedal behaviors occasionally seen in other primates. The morphological and behavioral commitment to bipedalism that characterized early hominids suggests unique ecological and historical circumstances as well (Fleagle 1999 p 528).

Some species of primates are intrinsically adapted to edge habitats and are, therefore, able to take advantage of changing environments. We hypothesize that the earliest hominids were edge species (see later) and that they exploited a terrestrial habitat due to a developing mosaic environment that included climate change. Rather than seeking the factors that caused early human ancestors to become bipedal, we propose that it was a preadaptation that already existed, and it was efficient in a new habitat; the successes or added advantages were simply a byproduct. Tattersall (2003) has arrived at a similar conclusion.

Besides bipedalism and limb use, there are also solid conjectures of what our earliest ancestors were like as far as body build, height, weight, and brain capacity. From an examination of the skeleton of Lucy and various A. afarensis specimens,
it seems there was a considerable size difference between males and females. Although the canines of both sexes were relatively small and not dagger-like, they were larger and longer in males than females. The range of body size for *A. afarensis* individuals is estimated to be 30–45 kg (Fleagle 1999); the height of adults has been estimated at 1.0–1.7 m (Klein 1999). Lucy, for example, stood slightly over 1-m tall and weighed around 30 kg (Conroy 2005). If these estimates are accurate, we can extrapolate that female *A. afarensis* were the size of male baboons and males were the size of female chimpanzees.

The cranial capacity of these hominids is estimated at 400–500 cc—about the size of a modern chimpanzee but twice as large as Miocene fossil apes. On average, australopithecines and modern chimpanzees have brains that are two to three times larger than similar-sized mammals, whereas in modern humans brain size is six to seven times larger than other mammals. Using the encephalization quotient (brain size relative to body size) as a measurement, the brain of *A. afarensis* was slightly larger in relation to its body than that of modern chimpanzees (EQ = 2.4 for *A. afarensis* versus 2.0 for chimpanzees) (Boaz 1997). Thus, our ancestors were mid- to relatively large-sized primates with brains slightly larger than any living nonhuman primate, although only a fraction bigger than modern chimpanzees.

There are many speculations about the external appearance of australopithecines. Johanson and Edey (1981) reconstructed Lucy as follows: small but extremely powerful; bones robust for her size; heavily-muscled; arms longer in proportion to her legs and trunk than modern humans; hands like modern humans but fingers curled more when in a relaxed position; head more apelike than humanlike with prognathic jaws and no chin; possibly more body hair in comparison to modern humans.

### 23.5 Habitat of our earliest ancestor

Although many early theories on the evolution of our earliest ancestors stress the importance of arid, savanna environments, these do not seem to be the primary habitats, according to the fossil record, until after 2 Ma. The African climate became more arid in the time between 12 and 5 Ma, and equatorial forests were undoubtedly shrinking (Conroy 2005). However, the process that led to this climatic phenomenon also greatly enlarged areas of transitional zones between forest and adjacent savanna. Closed woodland forests were still widespread in East Africa 3.5 Ma, whereas the proportion of dry shrub to grassland habitats began to increase around 1.8 Ma (de Menocal and Bloemendal 1995; Schekleton 1995).
It is in these transitional zones that behavioral and anatomical changes may have been initiated in early hominid evolution. The flora and fauna remains that are found in association with fossil hominids of this time period indicate a mixed, mosaic environment, ecologically diverse and subject to seasonal and yearly changes in vegetation (Potts 1996; Wolpoff 1998; Conroy 2005). These environments were wetter than those in which later fossil hominids are found, and most fossil sites of this early time period contained some type of water source such as rivers and lakes (White et al. 1994; Wolde Gabriel et al. 1994). For example, at Hadar in Ethiopia the mammalian fauna remains suggest that a lake existed, surrounded by marshy environments fed by rivers flowing off the Ethiopian escarpment (Conroy 2005). A mosaic of habitats existed at Hadar consisting of closed and open woodland, bushland, and grassland.

The earliest hominids appear to be associated with variegated fringe environments or edges between forest and grassland. These types of habitats usually contain animal and plant species of both the forest and the grassland, as well as species unique to the borders between the two. The species adapted to these transitional habitats are often referred to as edge species. During these earliest times, it appears that hominids began to take advantage of the growing fringe environments, lessening competition with their sibling ape species which were better adapted to exploit the dense forest, and thus partitioning the niche occupied by the parent species of both apes and hominids into two narrower and less overlapping adaptive zones (Klein 1999; Conroy 2005).

From available evidence, we speculate that our early ancestors were able to exploit a great variety of food resources but were mainly fruit-eaters, probably supplementing this diet with some young leaves and other plant parts, social insects, and a small amount of opportunistically captured small vertebrate prey—lizards, small snakes, birds, and mammals.

Several other species of primates are intrinsically adapted to edge habitats and are also able to take advantage of changing environments. Ring-tailed lemurs in Madagascar, African baboons and vervet monkeys, and some Asian macaques and langurs are nonhuman primate examples. These, not coincidentally, are some of the most common and numerous of all living primates other than humans. The macaque genus, for example, has the widest geographical distribution of any nonhuman primate in Asia. Many macaque species in Asia are endangered, but the ones that have the healthiest populations (e.g., long-tailed macaques, *Macaca fascicularis*, and rhesus macaques, *Macaca mulatta*) are edge-adapted.

Certain habitats may tend to impose specific behavioral repertoires. Many argue that the more similar the DNA, the more similar will be the behaviors between related species. In that case, chimps and bonobos might be the best prototype for early human ancestors. However, if ecology is paramount, then
chimps and bonobos may be less suitable prototypes (although some traits between these close relatives may still be important and phylogenetically conservative) and edge species may be the best models for early humans. Fox (1967 p 419) stated: “... the problem of taking the great apes as models lies in the fact of their forest ecologies. Most modern students of primate evolution agree that we should pay close attention to ecology in order to understand the selection pressures at work on the evolving primate lines. This has been shown to be crucial in understanding... evolution.”

Even if one were to learn everything about the hominid-ape common ancestor, many of the most crucial questions about distinctively hominid evolution would remain unanswered. Although there is a fairly impressive record of human fossils during the period of 7–2 Ma, there is a lack of chimpanzee fossils at these early sites. It seems likely, therefore, that chimpanzee ancestors did not inhabit these fringe environments and were likely restricted to more wet, closed forest ecosystems—areas where fossils are less likely to be preserved. Some populations of chimpanzees moved into more mosaic, open habitats relatively recently, long after humans had moved into more arid environments. Modern chimpanzees do not live in habitats in which modern humans lived in the past or are found today; the historical geographic range of chimpanzees is quite restricted, probably more restricted than even that of early humans before leaving Africa. In our opinion, the best primate models to use as a basis for extrapolation about behavioral characteristics of our earliest ancestors are modern primate species living in similar edge habitats.

23.6 The Macaque model

Macaques can be extremely good colonizers of edge habitats. The macaque genus spread throughout Asia before humans reached that continent (Delson 1980). By the time H. erectus arrived in Asia 1.8 Ma, most hominids were no longer edge species (our more recent ancestors were exploiting more open habitats by this date), so hominids likely did not displace the macaques. True “weed” species, we propose that the macaques are excellent models for reconstructing how our early ancestors may have lived.

Long-tailed macaques (M. fascicularis) are small edge species that spend a good proportion of time both in the trees and on the ground. They are omnivorous and very versatile in their locomotion, although mainly quadrupedal. The most widespread of any Southeast Asian monkey, they occur from Burma through Malaysia and Thailand to Vietnam, while offshore populations are found on Java, Borneo, and numerous smaller islands as far east as the Philippines.
and Timor. Throughout this area, broadleaf evergreen and other forest types are interspersed with secondary and disturbed habitats, and it is the latter that long-tailed macaques prefer. Virtually all of the studies of this species make note that they are most commonly found in secondary forest habitat, preferably near water (Southwick and Cadigan 1972; Kurland 1973; Rijksen 1978; Crockett and Wilson 1980; Wheatley 1980; Rodman 1981; Sussman and Tattersall 1986). The success of the long-tailed macaque throughout its extensive Asian distribution is widely credited to its being an “adaptable opportunist” (Mackinnon and Mackinnon 1980 p 187). Researchers emphasize that these monkeys are extremely adaptable and able to flourish in highly disturbed land.

There is a sizable long-tailed macaque population on the island of Mauritius in the southwest Indian Ocean (Sussman and Tattersall 1981, 1986). Although the original transport of the species from Asia to Mauritius is undocumented, it is likely that they were on board ships when the Portuguese first reached the island and were inadvertently or purposely introduced to this ecosystem. Cited from the first studies as an assertive colonizer of new habitat, the small number of original immigrants has increased to 40,000 animals—successfully illustrating a facility to colonize disturbed and varied habitats (Sussman and Tattersall 1986).

Long-tailed macaques are slender, active monkeys; average weight is 4–5 kg for females and 6–7.75 kg for males (Jamieson 1998). Their society is organized around matrilineal hierarchies. One or two dominant males are visible within the group, as well as some lower-ranking adult males, plus the adolescent and subadult male offspring of the females. At sexual maturity, males migrate to a new group. Female offspring are philopatric, mating with unrelated males who join their troop (Jamieson 1998).

Many of the Man the Hunter models ignore or minimize the role of females in human evolution. In many terrestrial and edge-adapted nonhuman primate species, such as long-tailed macaques and baboons, females are the core of society, remaining with their female relatives from birth to old age. Each matriline consists of several generations and can be placed in a dominance hierarchy. Highly social females inherit the rank of their mothers, so the troop organization remains relatively stable over time.

Man the Hunter scenarios typically depict male hunters as leaders, innovators, tool makers, and tool users. Since these aspects of gender specificity may never be revealed in the fossil record, we believe it may be justifiable to construct theories based on our primate relatives. When Japanese macaques were first studied in the wild, it was the young females who started innovative behaviors such as new ways of processing food (Kawai 1958). Chimpanzee tools are made mainly by females and used mainly in gathering activities such as nut-cracking and termite-fishing; it is also the female chimpanzees who teach the
next generation how to use these tools (Boesch and Boesch-Acherman 2000; Sanz 2004). Furthermore, in most primates, females are the repositories of group knowledge concerning home ranges and scarce resources. Group knowledge and traditions are passed on from mother to offspring, and stability of the group, both in the present and over time, is often accomplished through female associations (Zihlman 1997).

In all primate species, males, females, or both sexes migrate between groups when they reach sexual maturity, thus maintaining genetic diversity within the population. In most edge species, such as long-tailed macaques, at sexual maturity males will leave the troop they were born into and seek an entirely new group of females who inhabit a different home range. Males in this kind of society will continue to migrate between groups throughout their lifetime. This situation portends a constant need for males to develop new social networks; often forming “friendships” with females in a new group as an entry strategy (Altmann 1980; Strum 2001).

In most primates adapted to edge environments, it is the males who migrate. However, in the closest genetic relatives of humans, the gorillas, chimpanzees, and bonobos, females normally change groups when they mature. This appears to be a phylogenetically conservative characteristic among hominoids which makes it possible that among our earliest ancestors females, not males, migrated between groups. However, most modern human foragers are multilocal with individuals residing with their maternal relatives at times and with their paternal relatives at other times, or sometimes with neither (Marlowe 2005).

The ability of edge species to exploit a wide variety of environments is accompanied by a substantial flexibility of behavior. Long-tailed macaques appear to be primarily arboreal where suitable vegetation exists but will descend to the ground along riverbanks, seashores, and in open areas. In some portions of their recently colonized range, such as Mauritius, they are highly terrestrial (Sussman and Tattersall 1981). They are eclectic omnivores with a distinct preference for fruit, but the variety of habitat they exploit is reflected in a wide selection of food items besides fruit, such as leaves, grasses, seeds, flowers, buds, shoots, mushrooms, water plants, gum, sap, bark, insects, snails, shellfish, bird eggs, and small vertebrates (Sussman and Tattersall 1981; Yeager 1996; Shaffer and Sussman 2005). Human-disturbed habitat or proximity to human settlements is not avoided; rather, they tend to live in proximity to humans throughout their range, which results in crop raiding of sugarcane, rice, cassava, and taro fields.

Long-tailed macaques live in large multimale, multifemale groups of up to 80 individuals, although in some areas groups are much smaller. They show distinct flexibility in structure; the large basic social unit tends to split up into smaller subgroups for daytime-foraging activities (Jamieson 1998; Sussman personal
observation). Subgroups may be all males but most often consist of adult males accompanying females and their young offspring. The number and size of subgroups tends to vary with the season and resource availability (Jamieson 1998). The entire troop reforms each evening and returns to the same sleeping site each night, usually on the edge of a water source. Because of their unique behavior of returning to a home base each night, long-tailed macaques could be labeled a “refuging” species.

### 23.7 Fossils and living primates

Looking at the fossil evidence, it is apparent that human ancestors, living between 7 and 2.5 Ma, were intermediate-sized primates, not smaller than male baboons or larger than female chimpanzees. Given their relative brain size, human ancestors were at least as clever as the great apes of today. They had diverse locomotor abilities, exploiting both terrestrial and arboreal habitats. They used climbing and suspensory postures when traveling in the trees and were bipedal when on the ground. We believe that their bipedalism was a preadaptation, but walking on two feet freed the arms and hands and proved to be advantageous in a number of ways.

Given their relatively small size and small canines, there is no reason to think that our early ancestors were any less vulnerable to predation than are modern monkeys—some of which have yearly predation rates generally comparable to gazelles, antelopes, or deer living in similar environments (Hart 2000). Edge species can be highly vulnerable to predation and because of this usually live in relatively large social groups with many adult males and females; adult males often serve as sentinels and provide protection against predators (Hart 2000). Because a primate group with only 1 male and 10 females can have the same reproductive output as a group with 10 males and 10 females, often the male acts as first line of defense; if a male is lost there are other males to take his place. If a sexually mature female is taken by a predator, then she and all her potential offspring (and living-dependent infants) are lost.

We propose that our early human ancestors may have lived in multimale, multifemale groups of variable size that had the capacity of splitting up, depending on the availability of food, and reforming each evening at home base refuges. It seems highly likely that females carried the young, conducted most of the socialization of the young, were repositories of group knowledge, had cognitive maps of the home range and its resources, were the center of society and the core of group stability, and spread innovations, techniques, and knowledge through the group and on to the next generation. However, certain facts, such as the exact size of the groups and subgroups, whether males or females migrated from their natal group, the internal structure of the group (whether matrilineal or formed...
along male kinship lines), would be impossible to determine accurately. Indica-
tions of these social parameters cannot be found in the fossil record and are quite
variable even in closely related living primates.

In sum, the best archetype of early humans may be a multimale, group-
living, mid-sized, omnivorous, quite vulnerable creature living in an edge habitat
near a large water source. These primates may well have been a refuging species
returning to the same well-protected sleeping site each night. Most modern
foragers are considered central place foragers, focusing their activities around a
central place, as are many birds, social carnivores, and primates (Marlowe 2005).
This early hominid was adept at using both the trees and the ground, but when
it exploited the terrestrial niche, it had upright posture and was bipedal. It
depended mainly on fruit, including both soft fruits and some that were quite
brittle or hard, but also ate herbs, grasses, and seeds, and gritty foods such as
roots, rhizomes, and tubers. A very small proportion of its diet was made up of
animal protein, mainly social insects (ants and termites) and, occasionally, small
vertebrates captured opportunistically. Our earliest ancestors did not regularly
hunt for meat and could neither process it dentally nor physiologically.

Like all other primates, and especially ground-living and edge species, these
eyearl humans were very vulnerable to predators and this trait did not diminish
greatly over time (Hart and Sussman 2005). Fossil evidence to this effect exists
from South Africa, from the Zhoukoudian cave in China, skulls uncovered at
Dmanisi in the Republic of Georgia, and a new fossil from Olorgesailie, Kenya
(Brain 1981; Berger and Clarke 1995; Gabunia et al. 2000; Boaz and Ciochon
2001; Small 2005).

23.8 Man the Hunted

Given that the earliest hominid ancestors were medium-sized primates who did
not have the morphological characteristics to fight off the many predators that
lived then—and given that they lived in edge environments which incorporate
open areas and wooded forests near rivers—then, like other primates, they were
vulnerable to predation. Because of this, we hypothesize that rates of predation
were just as high in our early ancestors as they are in modern species of primates
and our origins are those of a hunted species (Hart and Sussman 2005).

Protection from predation is one of the most important aspects of group-
living, and we believe this was true of our earliest ancestors. Based on the long-
tailed macaque model, it is probable that social groups of early hominids were
organized in a way that allowed efficient exploitation of a highly variable
and changing environment and also protected its members of the group from
predators. If the human lineage started out as Man the Hunted, we propose a
number of strategies for protection from predators based on the behavior and social organization we observe in long-tailed macaques. These include:

- Relatively large groups composed of 25–75 individuals: since safety lies in numbers, one of the main reasons all diurnal primates live in groups is predator protection which provides more eyes and ears alert to the presence of predators as a first line of defense. In his research on modern human foragers, Marlowe (2005) found that the median group size is 30 individuals.

- Versatile locomotion that exploits both arboreal and terrestrial milieus: the major advantage of agility in the use of diverse habitats is safety in trees and dense underbrush. An added advantage of upright posture is the ability to scan for predators.

- Flexible social organization: for example, gathering scarce resources in small groups but reuniting as a larger group when predation requires strength in numbers allows small groups to quickly disperse and hide while large groups can mob and intimidate predators. Again, modern human foragers fit this pattern of flexibility (Marlowe 2005).

- Multimale social structure: this demographic feature provides more male protection when traveling through open areas and when the group settles in evening or midday. When large groups break into subgroups, females and young are accompanied by one or more large males.

- Males as sentinels: males are usually larger in edge species. Upright posture adds to the appearance of large size and allows for better vigilance, as well as waving arms, brandishing sticks, and throwing stones. Being more expendable than females, males mob or attack predators.

- Careful selection of sleeping sites: refuging species bring the whole group together at night in a safe area. Staying in very dense vegetation during daytime rest periods is essential. Males stay on high alert during these inactive periods and when the group is on the move.

- Staying one step ahead of predators: intelligence endows primates with the ability to monitor the environment, communicate with other group members, and implement effective antipredator defenses (Hart and Sussman 2005).

This reconstruction of the behavior and ecology of our earliest hominid ancestors reflects the pervasive influence of large, dangerous predators throughout human evolution. Many circumstances have been proposed as a catalyst for the evolution of the human species—competition for resources, intellectual capacity, male–male conflicts, and hunting. However, looking at our primate relatives and the fossil record, we believe that predation pressure was one of the most critical components in shaping the evolution of our earliest ancestors.

24 Modeling the Past: The Paleoethnological Evidence

Paolo Biagi

Abstract

This chapter considers the earliest Paleolithic, Oldowan (Mode 1), and Acheulean (Mode 2) Cultures of the Old Continent and the traces left by the earliest hominids since their departure from Africa. According to the more recent archeological data, they seem to have followed two main dispersal routes across the Arabian Peninsula toward the Levant, to the north, and the Indian subcontinent, to the east. According to the discoveries currently underway at Dmanisi in the Caucasus, the first Paleolithic settlement of Europe is dated to some 1.75 Myr, which indicates that the first “out of Africa” took place at least slightly before this date. The data available for Western Europe show that the first Paleolithic sites can be attributed to a period around 1.0 Myr. The first well-defined “structural remains” so far discovered in Europe are those of Isernia La Pineta in southern Italy, where a semicircular artificial platform made of stone boulders and animal bones has been excavated. The first hand-thrown hunting weapons employed by Homo erectus come from the site of Schoeningen in north Germany, where the occurrence of wooden spears, more than 2-m long, has been recorded for the first time from a site attributed to some 0.37 Myr. At roughly, the same time H. erectus is supposed to have begun the domestication of fire. Although most of the archeological finds of these ages consist of chipped stone artifacts, indications of art demonstrations seem to be already present in the Acheulean of Africa and the Indian subcontinent.

24.1 Introduction

The aim of this chapter is to review the current evidence for the paleoethnology of the early hominids who inhabited the Old World from the time of their appearance up to the end of the Middle Pleistocene. Although the data presently available are not abundant, there is no doubt that they are of key importance for
the understanding of early hominid behavior and lifestyles. The evidence concerned is limited in most cases to stone tools and their contexts (Clark 1968 p 277), almost exclusively due to natural and environmental factors both physical and biological (Stiles 1998 p 134). Early stone tool assemblages are often associated with alluvial sedimentary processes (Isaac 1967) related to the geographic and geomorphologic location and distribution of the (sometimes ephemeral) sites that in many cases are limited to the stone tools themselves, and possibly to organogenic tools and the faunal remains derived from hunting and scavenging activities. Nevertheless, the excavations carried out during the last 50 years, and the study of the settlement structures and tool assemblages of the Early Paleolithic sites of the Old World, “have shown that it is quite possible to find sealed occupation sites that have suffered little or no natural disturbance before or after burial” (Clark 1968 p 276).

As far as the remains of material culture and their chronotypological characteristics are concerned, this chapter deals almost exclusively with Mode 1 (Oldowan) and Mode 2 (Acheulean) complexes (Clark 1994). Tools belonging to these two “modes” have been collected from a great number of sites, which are distributed between East Africa and the Indian subcontinent in the southeast, and Europe in the northwest (Otte 2000 p 111).

### 24.2 Out of Africa

Much has been published dealing with the spread of the first hominids and the radiometric dating(s) of the “out of Africa” dispersal(s) (Chauhan 2005). Nevertheless many questions are still unresolved, since “the triggers for the movement of humans out of Africa are not well known” (Bar-Yosef and Belfer-Cohen 2000 p 81). This state of affairs results from the absence or scarcity of reliable data from some of the key territories that hominids must undoubtedly have crossed to reach Eurasia (Petraglia 2003: Figure 12).

This is the case for Arabia, from which little information is currently available, especially from the southern portions of the peninsula, more precisely Yemen (Dhofar) and Oman. Effectively, the Early Paleolithic sites discovered in these countries come from a few, restricted areas where intensive surveys and excavations have been carried out in the last two decades (Amirkhanov 1991; Cremaschi and Negrino 2002; Whalen et al. 2002; Whalen and Fritz 2004). Even though many of them are represented by surface finds, the Soviet–Yemeni Archaeological Mission excavated thick sequences in some caves of southeast Yemen, close to the Dhofar border. This led to the discovery of stratified complexes, which Amirkhanov (1994 p 218) attributed to the pre-Acheulean (Oldowan: Mode 1)
and Acheulean (Mode 2) periods. In this context, the only tool bearing evident traces of use, from the lowermost layers of Al-Guza Cave in Yemen (Amirkhanov 1991 p 107), is of unique importance. This is the only pre-Acheulean worn chopper so far known from the entire south Arabian Peninsula.

Although the Early Paleolithic sites so far discovered in this region are few, south Arabia is claimed to represent one of the key routes followed by the first hominids once they started to move out of Africa reaching the central territories of the Indian subcontinent, not later than 1.0 Myr (Bar-Yosef and Belfer-Cohen 2000 p 82). A second route is said to have been followed “across the Sinai into western Asia . . . although this has not been adequately detailed to date” (Bar-Yosef 1994 p 237; Petraglia 2003 pp 168–169), where the oldest site known to date is located at Ubeidiya (Bar-Yosef 1995 p 250) (Figure 24.1).

The two radiometric dates so far available from Dmanisi (Figure 24.2) in the Georgian Caucasus (Gabunia et al. 1999) demonstrate that this dispersal took place not later than 1.8 Myr (Gabunia 2000 p 43). Nevertheless “le mouvement oriental paraît à la fois beaucoup plus complexe et, surtout, beaucoup plus ancien qu’en Europe” (Otte 2000 p 108). Fortunately, the number of discoveries of Lower Pleistocene sites from this continent is systematically increasing (de Lumley 1976; Agustí et al. 2000; Mussi 2001 p 20).Although the absolute age of some of these

Figure 24.1

sites is problematic (Santonja and Villa 1990 p 54), many are undoubtedly much older than supposed only a few years ago (Roebroeks and van Kolfschoten 1994 p 500).

24.3 Chipped stone assemblages

24.3.1 Bifaces and other tools

As pointed out by Gowlett (2005 p 51), “East Africa is the key territory for examining the Oldowan and early Acheulean,” in which the first “bifacial tools were created about 1.5 million years ago” (Porr 2005 p 68) by Homo ergaster, as a consequence of a complex series of behavioral, economic, and social factors whose complexity has been pointed out by Porr (2005 p 77). Until recently, however, they have been considered almost exclusively in the context of “artefacts as a functional form that varies sometimes according to raw material considerations and is manufactured with a recurrent technology within broader parameters” (Ashton and McNabb 1993 p 190). But the fact that the manufacture of such tools continued for some 1.25 Myr indicates their importance, most probably not only as cutting and/or scavenging weapons (Domínguez-Rodrigo 2002) but also as social indicators independent of their functional meaning(s). According to Draper (1985 p 7), “we could imagine a situation where an Early
Paleolithic hominid might have fabricated a portable cutting tool for scavenging remnant meat from carnivore kills” that “was produced because a Middle Pleistocene knapper . . . was disposed to work stone in a way that produced an object we call a handaxe” (Hopkinson and White 2005 p 21). The high variability (Sinclair and McNabb 2005 p 185), the typological and dimensional characteristics (Isaac 1977), and the “wide temporal and geographic distribution” (Wynn 1995 p 11) of these tools have been noted by many authors, but from different perspectives and with different aims (Bordes 1968 p 23; Camps 1979; Petraglia 1998 p 371; McNabb et al. 2004; Hopkinson and White 2005) (Figures 24.3 and 24.4).

Although the complexity involved in the production of the lithic artifacts has been openly questioned (Hassan 1988 p 281), and the analysis of manufacturing techniques and debitage dispersal across the earliest Paleolithic sites (Gowlett 2005; Petraglia et al. 2005) is still rarely applied by the field archeologists, a few interesting exceptions should be mentioned. Among these is the MNK chert factory site in the Olduvai Gorge (Tanzania), which is dated to some 1.6 Myr. Here chipped stone artifacts, obtained from both local and imported raw materials, show a complex sequence of activities carried out by “early man working a raw material chosen for its technological properties brought to a central locality from diverse sources” (Stiles et al. 1974). FxJi50, in north Kenya, is a site 1.5 Myr old that “consists of a patch of stone artefacts interspersed with broken-up fragments of bone” (Bunn et al. 1980 p 111), whose precise function is still difficult to define. The chipped stone assemblage, which is composed of flaked cobbles and flakes, partly obtained on the spot, “has proved to consist of several dense clusters of material that interconnect with each other” (Bunn et al. 1980 p 114). This is one of the earliest Paleolithic sites from which “the close association (of bones) with artefacts and the presence of butchering marks suggest that the toolmakers were the first accumulating agency” (Bunn et al. 1980 p 125). This picture is rather unusual, if we consider that “for most of the sites excavated and reported we do not have certain indications of any specific activities that characterize them, and in very few instances has localization of subsidiary tool kits within a floor even been claimed” (Isaac 1972 p 185) and that the interpretation of the variability of the spatial distribution pattern of the tools (Whallon 1973 p 117) within a site surface is often difficult (Keeley 1991 p 258).

### 24.3.2 Raw material, workshops, and quarries

When detailed recording methods have been applied, for instance, in the case of some localities excavated in the Indian subcontinent, they have revealed that characteristic tools, among them hand axes, cores, hammerstones, and different
Figure 24.3
Variation among lower Paleolithic biface assemblages of eastern Asia and south Asia. The dashed line represents the Movius line, the traditional demarcation between Mode 1 (Oldowan) and Mode 2 (Acheulean) industries (after Petraglia 1998: Figure 11.8)
dimensional classes of debitage flakes, systematically cluster in well-defined spots. This fact is useful in helping us to understand the development of the manufacturing areas within the site and the steps followed by the toolmakers during the production process (Hansen and Madsen 1983 p 51), especially when refitting methods are applied to the entire complex (Bergman et al. 1990 p 280). This is the case for the some Acheulean sites where different varieties of raw materials for tool production were available, including siliceous limestone (Isampur in India: Petraglia et al. 2005) and good quality chert from local outcrops (Rohri Hills in Sindh [Pakistan]: Biagi et al. 1996).

The evidence available from the second case shows that the waste products of large hand-axe-manufacturing workshops were scattered along the edges of circular sandy areas, which represent zones that were comprehensively cleared of limestone and chert boulders in Paleolithic times, before the manufacturing activities took place. For instance, the excavations carried out at Ziarat Pir Shaban 1 (Figure 24.4), one of the many Acheulean workshops discovered on the Rohri Hills that were exclusively devoted to the production of hand axes (Biagi et al.
1996) (Figure 24.6), has demonstrated that the perfect, finished bifaces were exclusively transported elsewhere, most probably to camps located in the adjacent Great Indian Desert that are at present buried beneath meters of sand inside thick, stabilized dunes (Misra and Rajaguru 1989). The maximum transfer distance is not known, due to the absence of any detailed research in the Thar Desert to the east of the hills, although the African parallels indicate transport between 15 and 100 km (Petraglia et al. 2005 p 208). A situation similar to that of the Rohri Hills is known at Ongar, near Hyderabad in lower Sindh (Pakistan), where Acheulean workshops were discovered in situ on the top of flat, limestone mesas (Figures 24.7 and 24.8). These deposits, very rich in seams of excellent chert, were exploited throughout the entire Paleolithic period, from the Acheulean onward (Biagi 2006).

As far as these two latter cases in Sindh are concerned, there is no doubt that the abundance of excellent, workable raw material played a fundamental role in attracting prehistoric populations at least since the Acheulean period (Biagi and Cremaschi 1988 p 425). The chert used by the earliest Paleolithic people was collected from large boulders or extracted from the top of the limestone terraces, although the accurate surveys carried out along the top of the mesas did not reveal any trace of Early Paleolithic mining activities.

Figure 24.7
Ongar (Sindh, Pakistan): C-shaped Acheulean chert factory area (photograph by P. Biagi)
As far as we know, the first Paleolithic chert quarries were opened by the Acheulean populations in Upper Egypt much earlier than until recently supposed (Smolla 1987 p 129). According to Vermeersch et al. (1995 p 22), “a few kilometres south of the Dandara temple ... a hill was clearly subjected to chert extraction by Acheulian people,” given the presence of an extractive pit discovered during the excavation of a small trench in an area rich in Late Acheulean tools. In contrast, almost nothing is known of the Acheulean raw material procurement systems in this region, which yielded abundant traces of Middle and Upper Paleolithic flint-mining activities (Vermeersch et al. 1997 p 191).

24.4 Habitation and other structural remains

Early Paleolithic Mode 1 and 2 sites are often characterized by “concentrations of debris, ... which ... have usually been interpreted to be the result of various processual phenomena” (Stiles 1998 p 133). Only a few of them, of varied chronology, have provided us with complex archeological evidence.
In Africa, we know that most of the earliest settlements were located in environments close to lake shores or, more commonly, along (former) river courses (Isaac 1976: Figure 3.3) (Figure 24.9). They have been interpreted as sites that are inhabited during only one season. The 1.75 Myr old Mode 1 site of DK, in Lower Bed I of the Olduvai Gorge (Leakey 1971 p 24 and Figure 7) yielded evident traces of man-made features, the most important of which consists of a circular structure of lava blocks, some 4.5 m in diameter (Figure 24.10), which the excavator interpreted as resembling “temporary structures often made by present-day nomadic peoples who build a low stone wall round their dwellings to serve either as windbreak or as a base to support upright branches which are over and covered with either skin or grass” (Leakey 1971 p 24).

The excavations carried out at Gomboré I, another Mode 1 site located at Melka Konturé in Ethiopia, brought to light a 230 m² living floor composed of rounded pebbles, rich in stone tools and faunal remains with an empty space of some 10 m² in between. The settlement, which has been dated at some 1.6 Myr, yielded a “higher platform . . . that . . . could have been roughly adapted for a shelter made of branches and animal skins” (Chavaillon 2004 p 263). The research carried out at this site revealed the occurrence of “small stone circles aligned north-south in the eastern sector . . . whose . . . external diameter . . .
Figure 24.10
Olduvai Gorge, site DK (Tanzania): Plan of the stone circle and the remains of the occupation surface: Stone artifacts shown in black, bones in outline (after Leakey 1971: Figure 7)
varies from 20 to 40 cm,” which were interpreted as possible “wedging stones for pegs set in rather hard soil” (Chavaillon and Chavaillon 2004 p 448). The presence of almost identical features was recorded also from the Acheulean site of Garba XII in the same region of Ethiopia.

Among the Mode 2 sites, extremely interesting and ideally preserved remains were brought to light at Isernia La Pineta in Molise (southern Italy). This site, whose chronology is still rather controversial (Mussi 2001 p 44), although the new radiometric dates indicate that the site is some 0.60 Myr years old (Coltorti et al., 2005; 19), extends over an area of some 30,000 m². It yielded traces of four different occupation layers from which more than 10,000 lithic artifacts, chipped from different raw materials, including limestone and chert from diverse sources, were collected (Peretto 1994). The site was located along the shores of a lake-basin, later buried by fluvial sediments. The most interesting structural remains were discovered during the beginning of the excavations, when an accumulation of animal bones and stone tools was uncovered on an almost semicircular paleosurface that was very rich in remains of Bison skulls and horns and Rhinoceros cranial bones and was delimited by large, travertine boulders (Giusberti et al. 1983 p 100) (>Figures 24.11–24.13). These discoveries might help interpret the spatial variability and activities carried out within this settlement site (Bartram et al. 1991). Remarkable differences among the lithic assemblages have been noticed between the different excavated areas, both in the raw material employed for producing artifacts and in the typology and dimension of the stone tools (>Figure 24.14) (Peretto 1983 p 81).

In central Italy, an interesting Mode 2 site dated to slightly later than 0.5 Myr, and with an assemblage consisting of both elephant long bones and stone bifacial hand axes, has been excavated at Fontana Ranuccio (Biddittu et al. 1979). The presence of bone hand axes is unique to the area (Biddittu 1982), where they become increasingly more common at the slightly later Mode 2 sites, like Castel di Guido in Latium (Radmilli and Boschian 1996).

Moving westward, the importance of the remains of structures, brought to light by H. de Lumley (1966) at Terra Amata, near Nice, in Provence, is represented by a shallow, oval-shaped hut-floor attributed to a Mode 2 group of people who inhabited the region around 0.4 Myr. Apart from the exceptional discovery of an almost “intact” habitation structure, the site is important because it yielded the first evident traces of a hearth indicating the domestication of fire by Paleolithic man in Europe, although traces of fire have long been known from a few Lower Pleistocene sites in East Africa (Clark and Harris 1985; Perles 1977).

The site of Bilzingsleben, in Germany, is of extreme importance for the study of the behavior of Homo erectus. The remains of three circular hut foundations, 3–4 m in diameter, with entrances systematically facing southeast, and with

workshop areas and fireplaces, have been discovered at this camp, dated to some 0.37 Myr (Figure 24.15). The importance of this site is indicated by the occurrence of the earliest so far known intentionally decorated bone objects that suggest, “non-utilitarian behaviours ... connected to reflexive thinking” (Mania and Mania 2005 p 110), as well as the indisputable traces of what is claimed to be a ritual paved area “with human skull fragments smashed in macerated condition” (Mania and Mania 2005 p 113). These discoveries demonstrate that “Homo erectus was therefore a human being that had a fully developed mind and culture, capable in creating his own socio-cultural environment with living structures, the use of fire and special activity areas” (Mania and Mania 2005 p 114). This also finds confirmation in the traces of Acheulean “art” both in Africa (Bednarik 2003) and in the Indian subcontinent (Bednarik 1990).

Gran Dolina at Atapuerca in Spain is an even earlier multilayered site, where some kind of ritual activity has been supposed to have taken place. The site yielded 150 human bone fragments, which have been attributed to four individuals, classified into the new form Homo antecessor. Some of the hominid
remains from Layer TD6, datable to at least 0.8 Myr, “show clear cut marks which have been interpreted as evidence of cannibalism” (Mosquera Martínez 1998 p 17).

Returning to Mediterranean France, this region is very rich in Lower Paleolithic sites, both open air and in caves. Among the latter, the internal deposits of Lazaret Cave (de Lumley 1969), a late Mode 2 Acheulean site attributed to some 0.12 Myr, yielded traces of a unique hut structure that has been reconstructed thanks to the occurrence of stone walls, fireplaces, and “masses of seaweeds possibly used as bedding for site occupants” (Mellars 1995 p 285). Although this site does not represent the earliest known evidence of cave structural remains in Eurasia, given the traces of much older man-made stonewalls in China (Fang et al. 2004: Figure 3) and Central Europe (Cyrek 2003: Figure 6), Lazaret is the

Bilzingsleben (Germany): Plan of the structuration of the Early Paleolithic camp: (a) limits of the excavated area, (b) geological fault lines, (c) shoreline, (d) sandy travertine sediments, (e) alluvial fan, (f) activity area at the lake shore, (g) outlines of living structures, (h) workshop areas, (i) special workshop area with traces of fire use, (J) circular paved area, (k) charcoal, (l) bone anvils, (m) stone with traces of heat, (n) bones with intentional markings, (o) linear arrangement of stones, (p) elephant tusk, (q) human skull fragments, (r) human tooth (after Mania and Mania 2005: Figure 7.1)
only one from which a detailed reconstruction of the events that took place inside the cave in Late Acheulean times have so far been possible.

24.5 Hunting weapons

Although, as mentioned earlier, the excavations carried out at Terra Amata in the 1960s had already revealed the presence of one single fireplace, the almost contemporary hunting site of Schöningen, in North Germany, yielded not only the remains of four hearths, one of which is some 1 m in diameter, but even a charred wooden stick, which might “have functioned as a firehook to feed the fire as well as a spit to roast, and also smoke, strips or pieces of meat” (Thieme 2005 p 127). This site is extremely important because of the occurrence of both the hunting weapons and the other wooden tools brought to light since 1994, which have radically revolutionized our view of the hunting methods and strategies followed by these hominids. The widely accepted view that *H. erectus* was unable to conceive and construct throwing weapons is contradicted by the discovery of sophisticated spears, even longer than 2 m, which suggest a long tradition in wood shaping and weapon craftsmanship showing that, in contrast to what was previously supposed, this species had already acquired that complex “sequence pattern of behavioural complexes” (Laughlin 1968 p 305) commonly labeled hunting, which represent “a way of life . . . that . . . has dominated the course of human evolution for hundreds of thousands of years” (Washburn and Lancaster 1968 p 293). More precisely “*Homo erectus* in the Middle Pleistocene was fully capable of organising, coordinating and successfully executing the hunting of big game animals in a group using long-distance weapons” (Thieme 2005 p 127). Although the Schöningen specimens are not the only wooden pointed tools so far recovered from an Early Paleolithic site in Europe, they undoubtedly represent the best preserved specimens discovered within a horse-hunting camp, a surface of some 3,500 m² of which has already been excavated.

Furthermore it is important to point out that already in the 1980s, Isaac (1984 p 17) had considered the use of throwing weapons by early hominids when he wrote “if the Lower Pleistocene tool-making hominids were hunting with equipment, they must have been using spears without stone tips (i.e. pointed staves or horns on staves), clubs, and, perhaps most important of all, thrown sticks and stones,” given that “none of the flaked stone artefacts can plausibly be regarded as ‘weapons’” (!). In effect it has been widely demonstrated that stone hand axes and cleavers are excellent butchering tools, but not hunting weapons, and, in particular, that “the sinuous retouched edge of a hand-axe retains its meat-cutting efficiency longer than a plain flake edge” (Isaac 1984 p 15).
24.6 Any ethnographic parallel?

Apart from the factors mentioned in the introduction, there are many others that make remains of early structures difficult to interpret. Among these are (1) the impossibility of “detailed” radiometric dating of the events that took place at short-term habitation sites and (2) the difficulty of proving the supposed contemporaneousness of the structural remains within an apparently “homogeneous” area. This is true even though it is widely assumed that “in inspecting the contents of a single structure, we can be fairly confident that the associated assemblage was all in use at one time, if not made at the same time” (Deetz 1968 p 283). Besides the two above-mentioned factors, there are two others of major importance regarding (1) the complete excavation of an occupation unit, an enterprise that has been successfully undertaken only on very few occasions (Clark 1968 p 277) and (2) the functional nature of the (seasonal) site itself (Hehmsoth-Le Mouël 1999 p 81).

With the exception of a limited number of cases reported by Clark for East Africa, and a few others which have been described in the preceding chapters, most sites are characterized by more or less dense concentrations of stone artifacts, differently disposed according to the activities performed (Stevenson 1991 p 280), reflecting “a complex system of extraction, manufacture, transport, use, resharpening, re-use, renewed transport and eventual discard” (Isaac 1986: Figure 15.6). Often, these have been subjected to a certain degree of weathering or represent a (complicated) sequence of depositional events that took place over a period of millennia. Isaac (1968 p 255) classified such concentrations in three main categories according to the vertical and/or horizontal diffusion of the stone tools. The first two of these “represent sporadic, intermittent occupations of great duration,” while the third “can probably be interpreted as fairly stable ‘home base.’”

Finally, ethnographic analogies are sometimes uncritically accepted by both archeologists and anthropologists, who often believe “that modern representatives of past stages of cultural development exist” (Freeman 1968 p 263), even though “any consideration of the implications for archeological interpretation of new ethnographic data . . . requires an examination of the general relationships between ethnographic observations and archeological reasoning” (Binford 1968 p 268).

25 Modeling the Past: The Linguistic Approach

Bernard Comrie

Abstract

First, traditional methods of comparative-historical linguistics are discussed as a means of reconstructing aspects of the past through linguistic means, with particular regard to the comparative method, the Neogrammarian hypothesis of the regularity of sound change, the construction of family trees of genealogically related languages, and linguistic paleontology as a means of reconstructing the physical and cultural environment in which the ancestor language was spoken. More detailed consideration is given to the reliability of different kinds of evidence in the application of these methods, especially problems arising from language contact and resulting horizontal rather than vertical transmission of innovations, and from the gradual splitting of an ancestor language into its descendants and the proposed wave theory model of this process. Emphasis is placed on the need for detailed and painstaking investigation in order to apply these methods. A critical discussion is then given of some more recently proposed methods, in particular mass comparison (with its lack of emphasis on the need to rely on the regularity of sound change), glottochronology (with its assumption of a constant rate of replacement for basic vocabulary), and typological comparison.

25.1 Introduction

Modeling and reconstructing the past is a traditional task in linguistics that goes back at least to the early nineteenth century, and which by the late nineteenth century had led to an impressive series of results, perhaps most notably the reliable identification of the Indo-European language family. This language family subsumes most of the languages spoken in Europe, northern South Asia, and some intermediate areas. The Indo-European hypothesis postulates that all these languages derive from a common ancestor by means of changes that can, to a large extent, be reconstructed even in the absence of direct attestation in historical documents. The methodology has also been applied to other languages, establishing other language families and a range of general principles governing
the ways in which languages can change. The subdiscipline of historical linguistics covers all aspects of language change. Historical-comparative linguistics is concerned more narrowly with those subparts of historical linguistics that are relevant to the grouping of languages into language families. The aim of this chapter is to describe and illustrate the basic principles that underlie historical-comparative linguistics as a tool for modeling the past, including both widely accepted methods and, with due caveats, some other methods that have been proposed more recently. A subsidiary aim is to try and explain why many linguists have been reluctant to employ some of these more recently suggested methods, often borrowed from other disciplines like archeology and genetics, while not forgetting that to understand motives is not necessarily to endorse them. Given the restricted space available, the account is necessarily illustrative rather than exhaustively argued. There are, incidentally, several standard introductions to (comparative-)historical linguistics, including Campbell (1998), which provide more detailed justification or references thereto.

25.2 Comparative method

25.2.1 Basic principles

The standard, most widely accepted method for establishing that languages are related via a common ancestor and for reconstructing that common ancestor and the changes separating the attested languages from their common ancestor is the comparative method. It will be useful to introduce the comparative method in several steps, some of which are provisional approximations that will be elaborated in later discussion. When two or more languages are claimed to descend from a common ancestor, it is usual in linguistics to say that these languages are “genetically related”; to avoid any possible confusion between this use of the term “genetic” and its use as the adjective corresponding to “gene,” “genetics” in biology, I will prefer a nontraditional terminology and say that such languages are “genealogically related.”

The comparative method resides in seeking traces of the putative common ancestor in the attested descendant languages. As a first approximation—which will require several refinements—we may say that if we find similarities in two or more languages that we are investigating, then we can, at least provisionally, attribute those similarities to their common ancestor. If we find more similarities between languages A and B than between either of these and C, then we may hypothesize further that A and B have a common ancestor—let us call it D—that is not shared by C, while D and C in turn share a common ancestor, which we may call E. This leads to a hierarchical structure as in Figure 25.1.
Historically, this can be interpreted as follows. At one time there was a single common ancestor, E. At some point in time, E splits into two descendant languages, D and C, because of different innovations taking place on each of the branches E–D and E–C. Subsequently, D in turn splits into two descendant languages, A and B, each in turn characterized by the different innovations of the branches D–A and D–B. The kind of hierarchical structure that results is known as the family tree of that particular language family.

In interpreting a linguistic family tree, it is important to bear several factors in mind, some of which will lead to refinements of the account given so far of the comparative method. One of the most important is that the branches of the diagram are defined in terms of common innovations. The justification for the node D, for instance, is not just that A and B share certain features that are attributable to their common ancestor D, but more specifically that these features are innovations that must have characterized D relative to E. A concrete example will make this clear. The Germanic languages (English, German, Swedish, etc.) are distinguished from other Indo-European languages by having $f$ where the other languages have $p$, compare English *father*, *fish*, *foot* with their Latin equivalents, respectively, *pater*, *piscis*, *pes*. Given that the languages that have $p$ in such words do not belong, on independent grounds that cannot be argued here, to a single branch, we can conclude that the $p$ in these words represents the initial state, and that the Germanic languages have undergone a shift from $p$ to $f$. (This is, incidentally, part of a radical change in the consonant system of Germanic languages relative to other Indo-European languages, known traditionally as Grimm’s Law.) Going back to the family tree discussed earlier and interpreting it in terms of the current discussion, we might say that A and B are English and German respectively, with D their common ancestor Proto-Germanic, while C is Latin, and E the common ancestor Proto-Indo-European. (It is usual to label the common ancestor of a group of languages with the prefix “Proto-.” Of course, there are many other Germanic languages, and many other Indo-European branches and languages, which are not represented in this partial diagram.)

The importance of common innovations, rather than just similarities, cannot be overestimated. In the example just discussed, the Germanic languages form a branch of the Indo-European family because they share a common innovation ($p > f$). The Indo-European languages that have $p$ do not form a
single branch, rather they are the residue of languages that have not undergone the shift that characterizes Germanic. This is, incidentally, at the root of many linguists’ discomfort with methods imported from other disciplines that rely simply on different states, e.g., with p and f as different states in the example just discussed, without considering which of the states is original and which is an innovation. In some cases, of course, it may be difficult or impossible to decide which of two states is the innovation, and in such cases it is correspondingly difficult or impossible to use that feature as the basis for constructing a tree.

25.2.2 Regularity of sound change

It will be noted that in the example just discussed of Grimm’s Law, it is not simply the case that we have a single instance of the correspondence p–f, in a single word, rather this same correspondence p–f is found in a range of words. In fact, we can take this principle further and say that, ideally, the same correspondence should hold in all words. This is the principle of the regularity of sound change, also known as the Neogrammariann hypothesis, one of the cornerstones of comparative-historical linguistics. More specifically, the principle of the regularity of sound change says that a given sound (in our example, p) will always change in the same way (in our example, to f) in the same environment. The addition of the condition “in the same environment” is crucial, because the same sound can develop differently in different environments. In the development to the Germanic languages, for instance, original p did not shift to f after s, so that we find correspondences like English spew, Latin spuere “to spit,” where Germanic p, not f, corresponds to p in other Indo-European languages. Although some linguists have recently questioned the value of the principle of the regularity of sound change, most notably those associated with the Greenberg approach (see 25.4.1), its value is nonetheless recognized by most scholars working in the area.

The principle of the regularity of sound change actually has a number of important corollaries for the application of the comparative method. Most importantly, what we are examining are not literally similarities across languages, but rather regular correspondences. First, items might be similar between two languages, but if this is not part of a regular pattern then they do not constitute a regular correspondence that can form the basis of establishing a family tree. Perhaps not surprisingly, words can sometimes resemble one another purely by chance. But some examples can be surprising if one is caught unaware. Take, for instance, English much and Spanish mucho, both with the same meaning and almost the same form. Even though English and Spanish are in fact genealogically related languages, though belonging to different branches of the Indo-European language family—Germanic and Italic (Romance), respectively—these two words
do not derive from a common ancestor, and as we trace their history back through time they look less and less like one another. English *much* is ultimately related etymologically to Latin *magnus* and Greek *mégas* “big,” while Spanish *mucho*, which derives from Latin *multum* “much,” is ultimately related to Greek *mála* “very.”

Conversely, words across languages can sometimes be related by means of regular correspondences even though the words themselves do not look particularly similar. It would be hard to find two words that look less like one another than the Armenian word for “two,” erku, and its Russian equivalent *dva*. In fact, however, the initial *erk-* of the Armenian form goes back quite regularly to Proto-Indo-European *dw-*, this same correspondence being found in a number of other words. (In historical linguistics, it is usual to prefix an asterisk to forms that are reconstructed, not attested. Armenian forms an independent branch of the Indo-European family, while Russian belongs to the Slavic, or Slavonic, branch. Note that English *two* is also related etymologically to the same Proto-Indo-European root. The examples in the last two paragraphs are taken from Ringe (1999), a useful reference in the present context in that it is intended for an interdisciplinary audience.) It will be observed that the establishment of regular correspondences, rather than superficial similarities, can be a painstaking process, one of the reasons why linguists are often suspicious of methods (such as those to be discussed in Section 25.4) that promise shortcuts.

There are, however, some exceptions to the principle of the regularity of sound change that seem just to have to be recognized as such. For instance, the Modern English pronoun *she* is almost certainly derived etymologically from Old English (Anglo-Saxon) *sēo* (with a number of attested variants in the vowel of the Old English word, but not the initial consonant), although the initial consonant of the Old English word would regularly have given Modern English initial *s-*, not *sh-. While there is a rather plausible series of idiosyncratic changes that will get from Old English *sēo* to Modern English *she*, this does involve going outside the strict limits of regular sound changes. This means that there is a certain amount of “noise” in historical reconstructions. While such noise is relatively small across brief time periods—Ringe (1999) estimates that between Old English and Modern English only 2% of sounds have changed irregularly—the accumulation of such exceptions across longer periods of time does mean that a limit will eventually be reached beyond which it is impossible to identify regular sound change because of the number of exceptions.

In some cases, we can provide an explanation for an irregular development that goes beyond the mere consideration of sounds. Consider, for example, the development into Modern English of the Old English verbs *cniawan* “to know,” past tense *cnēow*, and *māwan* “to mow,” past tense *mēow*. The forms of “know” regularly give Modern English *know*, past tense *knew*. By regular sound change,
the forms of “mow” would be *mow*, past tense *mew*, but in fact the past tense is *mowed*. What has happened here is that the originally irregular past tense of *mow* has been replaced by the regular formation in *-ed*, by a process that is known as analogy. Incidentally, *know* in Modern English also has an irregular past participle, *known*; in the case of *mow*, analogy has been partial, since both the expected irregular form *mown* and the analogical regular form *mowed* are found. Thus, although *mowed* is not the regular development of Old English *mēow*, we can explain how the Modern English form came about by appeal to other factors, admittedly such as do not apply regularly: the irregular past tense *knew* has not been regularized analogically.

### 25.2.3 Bases of cross-linguistic similarity

Chance is one way, in addition to common ancestry, in which words in two languages can show up as similar to one another. Another basis for similarity can be universal features of language, either in the sense of absolute universals, i.e., features that are common to all languages, or universal tendencies, i.e., features that have a widespread distribution independent of any particular historical event. If a feature is an absolute universal, then it of course plays no role in establishing the hierarchical structure of language relatedness, since all languages will by definition have the same value for this feature. Widespread ahistorical features are potentially more problematic, even if their number is probably rather restricted. One widespread cross-linguistic similarity that may well find its explanation here is the occurrence of words like, or at least beginning with, the sequence *ma* and meaning “mother”; compare, for instance, Latin *mater*, Mandarin Chinese *mā* and Haruai *mam*—Haruai is an indigenous language of highland New Guinea. While this might be historically determined, there is an alternative explanation, namely that this is one of the first sound sequences usually uttered by human infants, and that its interpretation to mean “mother” has been carried out independently by parents across the world. Of course, if this is the case, then there might be other interpretations that could be assigned to this sequence, and we find languages like Georgian, the national language of the Republic of Georgia, in which *mama* means not “mother” but “father.” (The Georgian for “mother” is, incidentally, *deda*.)

However, by far the most troubling factor in identifying common ancestry is the possibility of borrowing, whereby one language takes over a word from another language. (Borrowing can also apply to linguistic units other than words, e.g., syntactic constructions, but here it is primarily with words that we need to concern ourselves.) In the example, discussed earlier, of the regular
correspondence between Germanic \( f \) and \( p \) in other Indo-European languages, the careful reader might have observed that while this works well for English \textit{father}–Latin \textit{pater}, there seems to be a problem with English \textit{paternal}, which begins with a \( p \), instead of the expected \( f \) (cf. \textit{fatherly}). The explanation is that English \textit{paternal} is not transmitted vertically from Proto-Indo-European via Proto-Germanic but is rather transmitted horizontally by being borrowed from Latin, more accurately from Medieval Latin \textit{paternalis} (perhaps via French \textit{paternel}). In this particular case, we can trace fairly accurately the historical developments in English texts over the centuries so that the borrowing process that led to the Latin loan word \textit{paternal} in English can be readily identified. There are other criteria that can also be used. In particular, the regularity of sound change, more specifically the regular \( p–f \) correspondence between Latin and English, allows us at least to suspect that in English \textit{paternal} we are not dealing with a true etymological cognate of the Latin form, but rather with a loan, given the unexpected \( p–p \) correspondence without a preceding \( s \).

There can, however, be more difficult cases. In particular, if one language borrows a substantial chunk of vocabulary from another over a limited period of time, then the result may actually lead to a set of regular correspondences that would be misleading if one did not know the actual course of events. For instance, in the prehistoric period Finnish borrowed a number of words from Russian. Russian has an opposition between such consonants as \( p \) and \( b \) which is missing in Finnish but was interpreted by Finnish speakers in terms of their own opposition between \( pp \) and \( p \) between vowels, which leads to regular correspondences intervocalically between Russian and Finnish of \( p–pp, b–p \), as in Finnish \textit{pappi} < Russian \textit{popu˘} “priest,” Finnish \textit{liepä} < Russian \textit{xle˘bu˘} “bread.” (In the word-initial environment, both Russian \( b \) and \( p \) appear as \( p \) in Finnish loans of this period; Finnish does not allow word-initial \( pp \).) It should be noted that much of the current controversy between proponents and opponents of larger language families, such as Altaic (incorporating at least the Turkic, Mongolic, and Tungusic languages, perhaps also Korean and Japanese), hinges on whether similarities are attributed to common ancestry or borrowing.

Various attempts have been made to try and establish particular sets of vocabulary that are immune or, more probably, less susceptible to borrowing. For instance, it seems to be generally true that more basic vocabulary (such as \textit{arm} versus \textit{ulna}) is less likely to be borrowed, even if there are no concepts that can be characterized absolutely as unborrowable. Hitherto, the range of languages that has been considered in the formulation of such generalizations has been relatively restricted, in particular because until recently few language families have been investigated in sufficient detail to provide reliable etymological material. Recent advances in the etymological investigation of a wider range of
language families mean that it is now possible to test such hypotheses more reliably, and a project of just this nature, the Loanword Typology Project, is currently underway at the Max Planck Institute for Evolutionary Anthropology; see http://www.eva.mpg.de/lingua/files/lwt.html.

More generally, one can say that the problem in applying the comparative method is to find similarities or correspondences that are more plausibly attributed to common ancestry than to any other cause. One reason for choosing words as the basis of the method is that, a priori, we would not expect there to be any similarity between the shape of the word expressing a particular concept in one language and the shape of the corresponding word in another language, given the general principle of the arbitrariness (or conventionality) of the linguistic sign—there is no reason why a dog should be called dog rather than inu (Japanese) or mbwa (Swahili). A corollary of this is that, in applying the comparative method, we need to steer clear of phenomena that are likely to occur independently on different occasions. For instance, a sound change like $p > f$, which characterizes the Germanic languages, is relatively rare cross-linguistically, especially when taken in conjunction with the other sound changes that constitute Grimm's Law, and is therefore a good diagnostic as a common innovation. Changes that more frequently occur independently are less good diagnostics. For instance, in the history of both English and German a change has taken place that shifted the long vowel $\ddot{u}$ to the diphthong $au$, as in Modern English house, Modern German Haus, both pronounced /haus/, compare Old English and Old High German $h\ddot{u}s$. These two changes occurred independently, long after both English and German had split off from Proto-Germanic. Some dialects of both languages, such as Scots English and Swiss German, retain the undiphthongized long vowel. The “common innovation” of the diphthongization of $\ddot{u}$ to $au$ is therefore not usable as a criterion for grouping English and German together. In other words, the kinds of sound changes that are most useful are those that are least usual, since these are least likely to occur independently in two different historical events.

In the examples considered so far, the words that have been compared have usually been translation equivalents, i.e., in more informal terms have the same meaning. One example did, however, involve a slight change in meaning that was glossed over at the time, namely the pair English spew–Latin spuere, where the meanings are not quite identical, the English verb meaning “vomit,” the Latin verb “spit.” In this particular case, we happen to know from the historical record that the meaning of the English verb has undergone semantic change over the history of the English language, since in Old English it could also mean “spit.” Where languages are known to be related through correspondences that do not involve semantic shifts, then words that are similar in meaning and that show regular sound correspondences can usually be assumed to be good cognates, as in
the case of the English–Latin pair just mentioned. But the principles of semantic change are much less well worked out than those of sound change, and it is even possible that there may be no principles that can be set out with comparable rigor. To take one striking example, in less than 1,000 years the English adjective *nice* has shifted in meaning from “ignorant” to “good.” The historical development is well attested in English texts over the centuries, but this does not license us to claim an etymological relation between any phonetically similar pair of words meaning “ignorant” in one language and “good” in another. Many attempts to establish wide-ranging language families have been criticized for laxity in the treatment of the semantics of the items compared.

One final comment is in order. It is, of course, quite possible that a particular language, or even a branch of a language family, will have lost a word that existed in the protolanguage. It follows from this that words do not have to be found in all descendant languages, or even in all descendant branches in order to be projected back to the reconstructed protolanguage. Of course, if a word is found in only one language or branch, we have no evidence for projecting it back beyond that language or branch (even though we cannot exclude the possibility that it might go back further and have been lost, perhaps independently, in other languages and branches). How widespread a word needs to be across a language family in order to be reconstructed to the protolanguage is a complex question, though one that can be answered at least partially at least for some language families. In the case of Indo-European, for instance, a word found in a branch that is held to have separated earlier from the rest of the family (such as Anatolian, a now extinct branch whose best known constituent language is Hittite) and in the rest of the family can probably be reconstructed to the protolanguage. By contrast, a language found in even a number of the western branches might reflect a local innovation rather than an inheritance from the protolanguage.

### 25.2.4 Mixed languages

The discussion so far has assumed that any language can be assigned unequivocally to one language family or another. Parts of a language may be borrowed from another language belonging to a different family (or branch of the same family), but the very notion of borrowing assumes that there is a core to the language that remains genealogically inherited from its ancestor. An obvious question to arise is whether there can be exceptions to this generalization, i.e., languages that have taken substantial parts of their overall structure from different sources to such an extent that it is impossible or arbitrary to assign them to one language family rather than another. These would be mixed languages.
The question is discussed in detail in, for instance, Thomason and Kaufmann (1988).

For the vast majority of the world’s languages, there is no reason to think that they are not well behaved with respect to their genealogical affiliation, i.e., even though all languages have borrowed at least something from other languages with which they have been in contact, they have a clearly identifiable core that has been inherited by direct vertical transmission from a single ancestor language. But there are some exceptions to this generalization so that the possibility of mixed languages must be acknowledged. One set of languages that belongs here consists of the creole languages of the Caribbean such as Haitian Creole and Jamaican Creole. These languages take most of their vocabulary from a European language—French in the case of Haitian, English in the case of Jamaican—but have a grammatical structure that is very different from that of these European languages and more reminiscent of the grammatical structures of the West African languages that were the native languages of the slaves brought to the Caribbean and among whom the creole languages developed. Haitian Creole, for instance, is arguably a language with French vocabulary but Fongbe grammar. (Fongbe or Fon is the major indigenous language of Benin in West Africa.)

A perhaps even more striking example is Mitchif, spoken in North Dakota and scattered locations in Canada, since in Mitchif the dividing line between the different components cuts across the divide between vocabulary and grammar. In Mitchif, most verbs are of Cree origin, Cree being a member of the Algonquian family, one of the major indigenous language families of northeastern North America. Moreover, Mitchif verbs show the complex verb morphology that is characteristic of Algonquian languages. By contrast, nouns and adjectives are overwhelmingly of French origin and show characteristics of French noun phrases that are not found in Algonquian languages such as gender agreement between prenominal adjective and noun. While there are some exceptions, such as French-origin verbs and Cree-origin nouns (especially kin terms), the basic division is robust. A Mitchif sentence is thus basically a framework created by the Cree-origin verb into which one plugs noun phrases that are composed according to the rules of (somewhat modified) French. This makes it hard to say that Mitchif is either unequivocally an Algonquian or an Indo-European language. Of course, if one wants, it is always possible to force a decision, and in the case of Mitchif this would probably be in the direction of Algonquian, given that the Cree component provides the basic clause structure into which French-like noun phrases are inserted. But this is still very different from, say, the French loans into English, since one can perfectly well construct many sentences in English that completely lack French loans, whereas it is virtually impossible in Mitchif to construct sentences containing noun phrases without resorting to at least some French-derived vocabulary and grammar.
Although mixed languages provide exceptions, or at least challenges, to the simplistic assumption that every language is necessarily assigned to one and only one family, the study of such languages has provided important insights into linguistic history and prehistory. Bakker (1997), for instance, shows how a combination of linguistic and ethnographic-historical research can uncover much of the prehistory of how and why Mitchif arose in the way in which it did.

25.2.5 Linguistic paleontology

So far, we have seen how the comparative method can be used to establish that languages are genealogically related and to reconstruct their common ancestor—at least in principle, although the only example worked through in any detail involves the reconstruction of Proto-Indo-European *p as the common ancestor of Proto-Germanic *f and the corresponding *p found in most other Indo-European languages. It should be noted that the method cannot have as a possible result that two languages are not genealogically related, although it may have as a result that no genealogical relationship can be established—lack of evidence is not evidence of lack. This is already a significant result, since it shows, for instance, that the speakers of such modern languages as English, German, Spanish, Russian, and Armenian are linguistically the descendants of a single speech community, to which we have given the name Proto-Indo-European. But there are lots of things that are left open.

First, this says nothing about the biological ancestry of these speakers, and only biological investigations, in particular population genetics, will answer this question. There is no necessary link between the transmission of genes from generation to generation, which is a biological process, and the transmission of languages from generation to generation, which is a cultural process. And while early work suggested that there might be a close link between language families and families of populations (Cavalli-Sforza et al. 1988), later work has at least drawn our attention to the possibility of discrepancies (Nasidze et al. 2004), the latter suggesting, for instance, that while the Azerbaijani language belongs to the Turkic family, its speakers belong genetically rather with other populations of the Caucasus, which in turn suggests that a language shift took place whereby an indigenous population abandoned its heritage language for the incoming Turkic language. This is, incidentally, a nice illustration of how linguistics and genetics can cooperate in unraveling the details of prehistoric events.

Second, the method as described so far says nothing about the environment in which such reconstructed languages as Proto-Indo-European were spoken, whether by environment we mean the physical or the cultural environment. If, for instance, we were to discover an archeological site that lacked overtly...
linguistic evidence, such as inscriptions, we would have no way of knowing whether this might be plausibly identified with speakers of Proto-Indo-European or not. An extension of the comparative method, so-called linguistic paleontology, does, however, provide us with a tool of just this kind. Let us suppose that by using the comparative method as described so far we have established cognates for the word expressing a particular concept across a number of languages and are therefore confident that we can project the word back to the protolanguage. Crucially, this involves not only projecting the form but also its meaning, since any word (or more accurately: linguistic sign) is a combination of form and meaning. But this means that we can reconstruct not only, to a good degree of approximation, the forms that characterized the protolanguage but also the concepts that were around when that protolanguage was spoken. This is the field of linguistic paleontology. It has been applied to a number of language families, but we will here take examples from Indo-European.

Concepts that can be reconstructed to Proto-Indo-European provide significant evidence concerning the cultural environment in which this language was spoken; wide-ranging evidence and conclusions are presented in Mallory and Adams (1997). They show a society familiar, for instance, with textiles, metallurgy, wheeled vehicles, and agriculture, indeed probably quite advanced agriculture, given that a word can be reconstructed for “plow,” although the invention of the plow postdates the introduction of agriculture by around three millennia in the ancient Near East and adjacent Europe. It is important to note that linguistic paleontology is primarily a case of positive evidence. The fact that a particular concept cannot be reconstructed to the protolanguage does mean that the concept did not exist, only that there is no evidence to show that it did—but evidence may well have been lost to such an extent that an originally present concept can no longer be reconstructed. Many Indo-European branches and languages have, for instance, created new words for “hand,” to such an extent that it is difficult or impossible to reconstruct what the word for “hand” would have been in Proto-Indo-European, although we can surely assume that the speakers of this language did have hands.

25.3 Other traditional methods and representations

25.3.1 Internal reconstruction

Although the comparative method is the most widely used and most reliable method for reconstructing linguistic prehistory, there are other methods that can sometimes be brought into play, of which one forms part of the arsenal of
traditional historical-comparative linguistics, namely internal reconstruction. In order to explain this method, it will be useful to examine a historical change that took place in the history of the German language. At the earliest relevant stage voiced and voiceless stop consonants, such as \(d\) and \(t\), contrasted word-finally, as they still do in English *made* /meid/ versus *mate* /meit/. This state of affairs is still retained in German spelling, where we have for instance a distinction between *Bund* “union” and *bunt* “multicolored.” In Old High German these two words would also have been pronounced differently, but in the modern language they are both pronounced /bunt/, although they are still distinguished when a vowel follows within the same word, as in the genitive singular *Bundes* /bundəs/ versus the neuter adjective *buntes* /buntəs/. The reason for this state of affairs is a sound change that took place in the history of the German language and devoiced word-final stop consonants, including devoicing word-final /d/ to /t/. It will be seen from the examples given that different forms of the same word can be differentially affected so that we have a voiceless /t/ in *Bund* but a voiced /d/ in its genitive singular *Bundes*. Historically, a sound change applied in a particular environment (word-finally) but not elsewhere (in particular, before a vowel). If we just look at the modern language, namely the alternation between *Bund* /bunt/ and *Bundes* /bundəs/, then we have a so-called morphophonological (morphophonemic) alternation. In other words, environmentally conditioned sound changes can give rise to morphophonological alternations.

We can now turn this process on its head in order to reconstruct earlier states of a language, by hypothesizing that where we find a morphophonological alternation in an attested language, this must result from an earlier stage where there was no such alternation and an intervening sound change that affected the sound that alternates (/d/–/t/ in our example) in one environment but not the other. Now, this is far from foolproof argumentation; logically, it is the equivalent of trying to infer \(p\) from \(\text{if } p \text{ then } q \text{ and } q\). But nonetheless, it does provide a plausible account of how a language can come, synchronically (i.e., at a given point in time), to have a morphophonological alternation.

The method can actually be generalized somewhat. Whenever we have a situation that seems synchronically to be aberrant, we can ask what plausible chain of historical changes could have led from an expected situation to the currently observed unexpected situation. While the method has its risks, it has also paid off in at least one famous case. Saussure, better known as one of the founders of structural linguistics, was aware, like many linguists before him, of the kind of vowel alternations found in some Indo-European languages, such as in the Ancient Greek verb “to leave” with present tense *leípō* “I leave,” perfect *léloípa* “I have left,” aorist *èlìpon* “I left,” with the general pattern of alternations being \(e-o-Ø\), to which the name “Ablaut” is conventionally given in
Indo-European studies. Saussure noticed that some verbs are apparently exceptional, in particular in having the vowel *a* or *o* for expected *e*. He posited that the unexpected vocalism was the result of a sound that was originally adjacent to the vowel in question, that had affected the quality of the vowel (e.g., changing *e* to *a*), and had subsequently been lost; these “lost” sounds are now conventionally referred to as laryngeals. At the time of Saussure’s publication (1879), this was considered pure conjecture, but when later the Hittite language was deciphered and shown to be Indo-European, it turned out that Hittite had the consonant *h* in many of the places where Saussure had predicted the presence of a laryngeal.

25.3.2 Wave model

The family tree model of linguistic relatedness presented in Section 25.2.1 is the basic method used in order to represent genealogical relationships among languages. Nonetheless, there is a clear sense in which it is unrealistic. It seems to say that at a particular point in time, a language splits into two languages such that those two languages no longer have anything to do with one another. Under certain specific circumstances this might be plausible, for instance, if a speech community splits into two by one part going by boat to a distant island and never returning or being followed by those left behind, but this is clearly unlikely to be the normal state of affairs. Rather, what one finds is a gradual breakup of a speech community, with differences gradually increasing and fault lines slowly developing that may, subsequently, give rise to distinct languages and, eventually, even distinct branches of a language family. But unless and until this fission finally takes place, the picture one has is not so much of a family tree as of a patchwork of differences that crosscut one another, making the construction of a single family tree unjustifiable.

An example from the history of English will illustrate the general point. Two innovations that differentiate Modern English from Middle English (the language of, for instance, Chaucer) are (1) the diphthongization of the long vowel ā to give *au* as in *house* and (2) the replacement of the inherited third person plural pronouns by forms borrowed from Old Norse and which ultimately give rise to Modern English *they*, *them*, *their*. Innovation (1) spread from the south of the English-speaking area to the north, while innovation (2) spread from the north to the south. Let us go back to the period when these were ongoing changes and take a variety of English that has undergone both changes (henceforth “Middle”) and compare it with varieties that have just undergone change (1) (henceforth “Southern”) or just undergone change (2) (henceforth “Northern”). Since both Middle and Southern have undergone change (1), they should be
grouped together under a single node of the family tree, and this node should not include Northern, which has not undergone change (1). But conversely, since both Middle and Northern have undergone change (2), they should be grouped together under a single node of the family tree to the exclusion of Southern, given that Southern does not share this innovation. But this leads to a contradiction, since there is no way to draw a well-formed tree that satisfies both requirements. Rather, the results of the innovations can be diagramed as waves emanating from a particular starting point (the south for (1), the north for (2)) and overlapping in the middle.

Wave models are particularly useful in diagramming relations among closely related language varieties that are still in contact, and maps of dialects of a single language are often a good illustration of the use to which the wave model can be put. (It should, however, be noted that dialect maps often just show the geographical distribution of different variants without indicating which is the innovation, thus abstracting away from a representation of historical change.) The same can be true of closely related varieties that are considered distinct languages, often for reasons as much political or social as linguistic, if not more so. More generally, wave diagrams provide a more accurate model of reality “on the ground” as a linguistic area is in the process of undergoing internal differentiation. Subsequent changes, in particular, the loss of intermediate varieties as more prestigious varieties spread, will typically later override this picture to give clearer boundaries and a situation that can ultimately be diagramed by means of family trees; a more detailed discussion of how this can happen, with particular reference to the differentiation of the major branches of the Indo-European family, is given in Garrett (1999). But even after this differentiation has taken place, there can still be residual features that override the neat representation implied by the family tree. Within Indo-European, for instance, Slavic languages share some features with Germanic, other features with Indo-Iranian, although there is no overall subgrouping defined by shared innovations that includes all of Slavic, Germanic, and Indo-Iranian. More generally, the family tree model, with its implication of strict parthenogenesis, is a historical simplification that is extremely useful but should nonetheless not be elevated to the level of absolute truth.

25.4 Shortcuts and other new methods

25.4.1 Mass comparison

As will be appreciated from the discussion so far, traditional methods in historical linguistics require detailed investigation of the languages involved and the
painstaking construction and testing of hypotheses concerning the historical relations among them. Historical linguists will therefore often devote considerable effort to, for instance, the etymology of a particular word, arguing whether it is inherited from a particular ancestor language or a loan from outside, as evidence in arguing for genealogical relatedness among languages or for or against a particular subgrouping. It is therefore inevitably tempting to ask whether there are not shortcuts that could produce the general results that we are seeking without requiring us to go into all the detail of, for instance, trying to reconstruct the history of the pronoun *she* in English. One such method, championed by Greenberg (see, for instance, chapter 1 of Greenberg 1987) is mass comparison, which works by looking for similarities across a large number of languages. The method requires the compilation of comparative word lists, but does not require the establishment of regular sound correspondences, and thus does away with much of the apparatus required by the mainstream comparative method. Unfortunately, this also means that one loses the checks that this comparative method imposes, against, for instance, the inclusion of accidental look-alikes of the English *much*–Spanish *mucho* type, or the exclusion of regular correspondences that happen not to involve similar forms, as with Armenian *erku*–Russian *dva* “two.” While the method has been widely touted as a way of establishing more wide-ranging genealogical groupings than is possible using the comparative method, the results have not met with widespread approval, and it is perhaps unfortunate that they have too often been taken on faith by specialists in other disciplines.

But the attraction of mass comparison does point to a weakness of the comparative method, one that might or might not be able to be overcome by other methods. The accumulation of gaps and statistical inaccuracies as one reconstructs back in time means that eventually a point is reached where one can no longer be sure that such similarities as one detects between languages are the result of common ancestry rather than attributable to other factors, in particular chance and borrowing. It is hard to pin a date on this point—as will be noted in \textsection 25.4.2, there may well be no aspect of language structure that changes with the regularity of radioactive decay or the molecular clock—but it is empirically true that the languages families that have gained ready acceptance among linguists do not go back beyond about 10,000 years BP. Various factors can affect the exact date: for instance, one can usually go back further in time with a family of languages like Indo-European, which includes a large number of languages (about 200 on a fairly conservative count) with an internal division into a number of well-defined branches, than with a family that includes few languages or has little internal diversification. Nonetheless, it remains the case that most linguists are skeptical of claims going back further than around
10,000 years BP (and of a number of claims that do not go back that far), which is one of the reasons why several linguists are searching for new methods that might enable us to go beyond this limit.

### 25.4.2 Glottochronology

Although the comparative method leads to the construction of hierarchical tree diagrams that mirror, albeit with some simplification (as discussed in Section 25.3.2), the historical development of the descent of languages from common ancestors, the method does not in and of itself include any absolute chronology, so that the claim that English, German, and Swedish all descend from Proto-Germanic, and that Proto-Germanic and Proto-Slavic both descend from Proto-Indo-European, gives us no indication when Proto-Germanic, Proto-Slavic, or Proto-Indo-European was spoken. While linguists have not necessarily been reluctant to assign dates to such ancestor languages, this assignment has traditionally been intuitive, based on a “feeling” about how quickly languages change to produce particular degrees of inter-linguistic difference. For instance, Indo-Europeanists usually assign a date of about 6,000 years BP to Proto-Indo-European, but it is difficult or impossible to produce hard evidence for this date, although dates widely divergent from this can be considered implausible because, for instance, they would require language change during the early history of the family to have been much slower than the attested rate of change of any known language in the historical period—one reason for linguists’ skepticism toward dates for Proto-Indo-European of around 9,000 years BP.

In some disciplines there are methods of establishing quite reliable chronologies by making use of changes that are known to occur at fixed rates, such as the decay of radioactive materials in radiocarbon dating and other comparable techniques in archeology, or the molecular clock in genetics. Linguists have therefore sought after a comparable measuring stick in linguistic material. The method that has gained most widespread, though still quite limited, support is glottochronology. (A summary of both traditional and more innovative versions of glottochronology is given in Starostin (2000), which also includes criticism of traditional glottochronology and quite far-reaching proposals for modifications to the method to achieve greater reliability—modifications that still require testing.) The basic assumption of glottochronology is that for a certain portion of the vocabulary, the so-called basic vocabulary, there is a fixed rate of replacement, such that, for instance, after a thousand years 14% of this basic vocabulary will have been replaced. The choice of vocabulary might initially seem strange, since borrowing words from one language into another is perhaps the most
obvious sign of language contact. However, borrowing applies primarily to the nonbasic, culturally laden vocabulary, so that if one examines, for instance, Latin and French loans into English, there are only five in the 100-word “Swadesh list” (*animal, grease, mountain, person, round*), although overall English has borrowed substantially from these sources. The basic vocabulary, incidentally, is designed to include only terms that are part of basic universal human experience, though occasional infelicities creep into lists, such as “ice,” which does not occur naturally in most tropical regions, or “horn”—there are no indigenous horned animals in New Guinea.

One problem with the general method is that, in contrast to the situation with radioactive decay or genetic mutation, there is no principled reason to assume that the rate of replacement of basic vocabulary should be constant, in particular independent of social factors, which are known from experience to be the main determinants of the linguistic effects of language contact. Indeed, there may be particular circumstances in which social factors determine unusual rates of lexical replacement, even in basic vocabulary. Comrie (2000) discusses the case of the Haruai language of Highland New Guinea. In Haruai society, most personal names are ordinary words, and speakers are under a taboo not to utter the names of certain kin (in-laws, and father’s sister’s or mother’s brother’s children) or the ordinary words identical to these names, but rather to replace them with a synonymous lexical expression. Given the small size of the community, with about 1,000 speakers, this leads to a situation where words can go out of use quite rapidly because of broad kin networks relative to the small size of the speech community, typically being replaced by loans from adjacent languages. This has given rise to a situation where Haruai shares about the same percentage of basic vocabulary with Hagahai, to which it is genealogically related, as with Kobon, to which it is not demonstrably related. Starostin (2000) discusses a number of incorrect estimates of time depth that have been reached using glottochronology, at least in its traditional form.

There are various claims that have been made for glottochronology, with corresponding differences in how exactly the method is applied and interpreted. One implementation would search for look-alikes across languages, without considering in detail whether the words can actually be shown to be cognate (to descend from a common ancestor), calculate the percentage of such items across the whole list, and from this calculate the closeness of the genealogical relationship between the languages, and the date at which their common ancestor was spoken, always bearing in mind that very low percentages may be indistinguishable from chance similarity. This implementation suffers from the disadvantages of mass comparison discussed in Section 25.4.1. A more strict interpretation would be to calculate only the percentage of cognates—which
presupposes that one already knows that the languages are genealogically related—and then use this to calculate the time depths at which particular languages in the family separated off from other languages and therefore to draw a family tree with chronological labeling of the individual nodes. But all of this rests on the debatable notion of a fixed rate of change.

25.4.3 Typological comparison

The method of typological comparison has been championed by Nichols, for instance in Nichols (1992). A typological similarity across languages means a similarity not in form but rather in the overall structure of some part of the language. For instance, some languages like French, German, Russian, and Swahili have gender systems, whereby nouns are divided into two or more classes (genders) and other items, such as adjectives, have to change their form (agree) according to the gender of the noun with which they are associated. In French, for instance, the noun *fils* “boy” is masculine, and therefore requires a masculine definite article and adjective in *le bon fils* “the good son,” whereas *fille* “daughter” is feminine and requires a feminine definite article and adjective in *la bonne fille* “the good daughter.” By contrast, other languages, such as Hungarian and Persian, lack a gender system. (English, incidentally, does have a gender system, but with rather minimal scope: the third person singular pronouns *he, she, it* are selected in agreement with the noun to which they refer.) As can be seen in this example, typological classifications do not necessarily correspond to genealogical families: French, German, Russian, and Persian are all Indo-European, while Swahili and Hungarian are not.

The challenge posed by typological comparison as a tool in comparative-historical linguistics is to find typological features that are highly resistant to change, and are thus likely to remain constant across the languages of a particular family. If such features can be found that are even more persistent than the chronological limits on the comparative method, then we would be enabled to go further back into prehistory than is possible with that method.

Overall, the general result of typological comparison is that most typological features are very sensitive to language contact and thus cannot serve as indicators of genealogical relatedness. Indeed, one of the main results of the massive areal typological project reported in Haspelmath et al. (2005) is that languages are frequently more similar typologically to their neighbors than to their relatives. While some of the particular features proposed by Nichols have been criticized on the basis that they are subject to change by language contact, this does not exclude the possibility that there might be some typological
features that can be used as indicators of deep genealogical relations among languages.

One that has been proposed by Nichols is precisely the existence of gender systems, although the criterion is more complex than the mere presence versus absence of a gender system in a language. The absence of a gender system is not a plausible criterion for deep genealogical relatedness, since we know that languages can lose their gender systems, as has happened in the case of a number of Indo-European languages, such as Persian and Bengali (both belonging to the Indo-Iranian branch of the family, though almost at opposite western and eastern geographical extremes, respectively, of that branch), and Armenian. Moreover, languages can develop gender systems under contact with other languages that have gender systems, as has happened in a number of indigenous languages of Australia. But what may be more difficult is for a language spontaneously to develop a gender system. If this is so, then it would suggest that if a language that has a gender system is spoken in an area where other languages lack gender systems, then the genealogical relatives of that language should be sought with other languages having (or at least: having had) gender systems. A case in point would be Ket, the sole surviving language of the small Yeniseic family of western Siberia, which has a gender system, although all surrounding languages do not (these languages belong to the Uralic, Turkic, and Tungusic families—Russian does have a gender system but is a very recent intruder into this geographical space). The more extensive testing of Nichols’ specific claims about particular typological features remains a task for future research.

25.5 Conclusions

Linguistics has a distinguished history of establishing genealogical relationships among languages and thus providing evidence for the common linguistic ancestry of apparently diverse speech communities, as well as of reconstructing aspects of the culture and physical environment in which the speakers of the common ancestor language must have lived. The traditional methods require detailed and painstaking analysis of linguistic material and give at best questionable results when pushed back beyond 10,000 years BP (and in many cases well short of that range). New methods have been proposed that would enable linguists to go beyond the 10,000-year range, as well as to establish more reliable chronologies, but unfortunately these methods all suffer from questionable assumptions or proven inadequacies that have left most linguists skeptical of their validity. Nonetheless, interdisciplinary investigations involving linguistics, archeology,
and genetics have succeeded in throwing light on what until recently seemed to be intractable problems.

26 General Principles of Evolutionary Morphology

Gabriele A. Macho

Abstract

Anthropologists analyzing morphology for phylogenetic, functional, or behavioral purposes are confronted by a plethora of obstacles. Morphology is not free to vary but is subject to a number of constraints, which may be historical, developmental, and/or functional. This, together with the fact that the fossil record is scant, confounds meaningful interpretation of phylogenetic pathways and the reconstruction of function and behavior from fossilized remains. To overcome these difficulties, paleoanthropology is becoming increasingly inter- and multidisciplinary, whereby researchers draw on, and incorporate, approaches and findings obtained in other, sometimes very diverse disciplines. The purpose of this contribution is to review the constraints acting on morphology, the limitations faced when interpreting form/function and behavior from morphology, and the different approaches currently explored in paleoanthropology.

26.1 Introduction

With rare exceptions (e.g., endocasts, footprints, permafrost remains, peat bodies), only the hard tissues of the body become fossilized. Phylogenetic, functional, and behavioral interpretations of extinct taxa are thus almost exclusively based on analyses of bones and teeth. Such fossil remains are often incomplete and distorted, while taphonomic biases prevent a good representation of all parts of the body and/or functional units for detailed analyses (Grupe Volume 1 Chapter 7). It is therefore not surprising that the search for more fossil material is a priority in paleoanthropology (Brunet et al. 2002). These shortcomings aside, there exist other, more fundamental problems in analyzing and interpreting morphology. Resolving these issues is the aim of diverse research areas, whose integration has only just begun.

Morphology is highly constrained and determined by a cascade of interactions between genetic, epigenetic, and environmental factors modulated through past and present selective pressures (Atchley and Hall 1991). Consequently,
Morphology and function must not only be interpreted with respect to present-day function and the fitness it may confer to the species but should also be viewed against the backdrop of past form, function, and selective pressures. Phenotypic correlations due to pleiotropy, epigenetics or correlated selection, genetic drift, and co-option of characters for functions they were not initially selected for further compound a sound appraisal of morphology within a phylogenetic and functional framework. This, together with the fact that the developmental pathways for various structures are only poorly (if at all) understood, raises the question of whether form follows function or whether the reverse is just as likely. This is problematic as speciation is commonly associated with the acquisition of novel morphological characters and/or the exploitation of new ecological niches (Müller and Wagner 1991; Shubin 2002; but see Groves Volume 3 Chapter 18).

To overcome problems associated with the interpretation of morphological structures and variation in both extant and extinct populations, evolutionary studies have become increasingly multi- and interdisciplinary, although there are two main strands of investigations. First, evolutionary developmental biology, despite its long (and sometimes misguided) history (Haeckel 1866), is now a well-established discipline (Hall 1992; Wagner and Gauthier 1999; Love and Raff 2003). Such studies combine an experimental, developmental research protocol with comparative analyses of the fossil record to determine the developmental and phylogenetic pathways of morphological structures and the constraints acting on their formation. Despite their high power of resolution, such studies require expert knowledge, are time consuming, and are financially costly. Hence, they are restricted to a few laboratories and are not directly amenable to traditional paleoanthropological enquiry. Second, new functional and biomechanical tools are being incorporated in paleoanthropological research protocols (Thomason 1997) and promise to make a contribution to our understanding of the functional adaptations of extinct species.

A comprehensive review of both strands of enquiry is beyond the scope of this contribution. Instead, this chapter aims to highlight general problems associated with interpreting the morphology observed in fossil remains and the ways in which paleoanthropologists are currently investigating constraints, function, and behavior in the fossil record using a predominantly comparative approach.

### 26.2 Comparative morphology and constraints

Morphology is not free to vary but is subject to a number of developmental, physical, and historical constraints (Maynard Smith et al. 1985), also categorized
as generative or selective constraints (Richardson and Chipman 2003) (Figure 26.1). As the field of developmental biology progresses, new classes of genetic linkage constraints are being identified (Calabretta et al. 2003), which complicates the elucidation of evolutionary pathways even further. Yet, anthropological research is restricted to determining constraints through (1) quantitative methods, (2) by indirectly taking recourse to developmental pathways, and (3) through research designs that incorporate some (direct or natural) functional experiments.

### 26.2.1 Comparative morphology and evolutionary constraints

Phylogenetic systematics or cladistics is the main tool for reconstructing the phylogenetic relationships of taxa (Hennig 1966) and should precede paleobiological enquiry and functional analyses. While the strengths and weaknesses of this method, as well as its assumptions, are reviewed elsewhere in this handbook (Chapters 4–6) some limitations pertaining to the analysis and interpretation of morphology need to be briefly reiterated. Relevant for the discussion of constraints are issues regarding homology and the independence of characters. Analyses of homologous traits are at the heart of cladistic methodology, but experimental studies have provided unequivocal evidence for the hierarchical nature of homology, whereby homologies at one level of organization need not lead to homologies at another (Hall 1994; Raff 1996; Wagner and Gauthier 1999). Perhaps even more problematic for broader morphological enquiry is the assumption that anatomical traits are independent. This clearly is not the case and many characters are correlated as a result of pleiotropic effects (Riska and Atchley
1985; Riska 1989), correlated selection (Leroi et al. 1994), modular networks (Kauffman 1993; Salazar-Cuidad et al. 2000; Salazar-Cuidad and Jernvall 2002), and genetic linkage (Kangas et al. 2004). Such intercorrelations not only obscure the phylogenetic history but also hamper inferences made about function and behavior (see later). Determination of the covariance of various traits (Atchley and Hall 1991) is therefore of concern to paleoanthropologists.

On the basis of methodologies developed in population genetics, various quantitative tests are available to appraise the covariation and correlation of traits with the aim of inferring developmental and phylogenetic constraints (Cheverud et al. 1989). Such approaches are becoming increasingly popular in paleoanthropology and have recently been extended to the study of skull variation (Ackerman and Cheverud, 2000; Lieberman et al. 2004) and teeth (Hlusko et al. 2004). Such research designs not only shed light on the correlation of characters but also have the potential to estimate the rate at which characters can change during evolution. For example, Hlusko et al. (2004) have estimated that enamel thickness in baboons could theoretically double in only 50,000 generations. If correct, this character could be prone to homoplasy, and enamel thickness as a defining trait in hominins should be interpreted with caution.

Where more behavioral aspects of morphology are the focus of study, independent contrast, pioneered by Felsenstein (1985), is often the method of choice. Using a relatively simple algorithm, the independence (or otherwise) of two traits can be assessed. While originally used in zoological and behavioral research, recent paleoanthropological studies have begun to use this method also (MacLeod et al. 2003). Independent contrast is a powerful tool in evolutionary studies provided that the phylogenetic history of species is known: morphological traits under investigation must be mapped onto phylogenies. However, given that the primate phylogenies as well as their divergence times are subject of research themselves, the results obtained from such analyses should only be regarded as working hypotheses rather than providing conclusive information about the coevolution of morphological traits.

### 26.2.2 Comparative morphology and development constraints

#### 26.2.2.1 Teeth

Teeth are among the most abundant remains within the fossil record and contain a wealth of information for the taxonomists (Bown and Rose 1987; Haile-Selassie et al. 2004) and the functional morphologist (Hiiemae and Kay 1972; Kay 1977).
Owing to their pivotal role in the breakdown of food (Strait 1997), overall tooth size, shape, and enamel thickness are considered good indicators of the dietary niches exploited by extinct species (Janis and Fortelius 1988) and, when analyzed across lineages and clades, may even provide information about global climatic fluctuations (Fortelius et al. 2002). The importance of tooth morphology for functional inferences is thus undisputed, but the high level of homoplasy resulting from this fact compromises the usefulness of teeth for taxonomic purposes (Teaford et al. 2000). For example, the hypocone probably evolved independently more than 20 times (Hunter and Jernvall 1995), while thick enamel among primates could be the result of convergent evolution also (Janis and Fortelius 1988; Hlusko et al. 2004). Nonetheless, while overall tooth size and shape exhibits a considerable amount of homoplasy, the way in which these morphologies are achieved appears developmentally constrained.

Teeth are unique biological structures that retain a permanent record of aspects of their ontogeny, i.e., timing and rates of formation (Macho and Wood, 1995), as well as cell movement during odontogenesis (von Koenigswald and Sander 1997). Enamel and dentine matrix is secreted in a circadian manner during odontogenesis, whereby the daily increments are manifest in the mineralized tissue as cross-striations (enamel) and von Ebner lines (dentine). Analyses of these incremental lines in histological sections of teeth (or their surface manifestations) have allowed an appraisal of the timing of tooth development across extant and extinct primates (Bromage and Dean 1985). Apparently, dental crown formation times in primates are highly correlated with brain size and, consequently, other aspects of life history (Macho 2001; see also Hemmer Volume 1 Chapter 18), probably as a result of pleiotropic effects (Riska and Atchley 1985; Macho 2001; see also Hemmer Volume 1 Chapter 18). This mirrors restrictions observed in the timing and pattern of tooth eruption in primates (Smith 1989), as well as across mammals (Smith 2000). Thus overall analyses of dental development, both through histological sections of isolated teeth and eruption patterns, allow to address broader questions of brain and life history evolution, as well as developmental constraints. In addition, detailed analyses of the rates of enamel secretion (Beynon et al. 1991) could make possible an assessment of the heterochronic changes that occurred during dental evolution (McNamara 1995), although a satisfactory method for ascertaining the amount of enamel secreted by an ameloblast per day is still wanting.

Enamel prisms are formed by ameloblasts and trace the movement of ameloblasts during odontogenesis. While the mechanisms underlying the evolution of prismatic enamel, a characteristic trait of eutheria (von Koenigswald and Clemens 1992), are still the subject of investigation (von Koenigswald and Sander 1997), once evolved, prismatic enamel seems to have provided great potential for
further evolutionary modifications in response to selection pressures. As a case in point, the crossing-over of bundles of prisms, i.e., prism decussation, most probably evolved in large-bodied, thick-enamelled species as a crack-stopping mechanism (von Koenigswald et al. 1987). Until recently however, visualization and quantification of the complex three-dimensional arrangement of prisms has been wanting (Jiang et al. 2003; Macho et al. 2003a). Preliminary studies using this new technology indicate that, despite similarities in prism undulations, there are fundamental differences in the pattern of cell movement and the amount of prism deviation among even closely related primates (Jiang et al. 2003; Macho et al. 2003a). If confirmed, this could be exploited further for taxonomic and functional purposes (Rensberger 2000; Macho et al. 2005; see later).

26.2.2.2 Bone

Unlike enamel, bone is a plastic material, which continues to remodel throughout life in response to loads placed on it so that size and structure provide information about the functional adaptations of bone (Wolff 1892). For example, joints have evolved to confer both optimal orientation with regard to the direction of load and mobility, although the relative contribution of each of these aspects, as well as the magnitude of loads, remains uncertain. Cortical bone provides bending strength to the shafts of long bones. Overall scaling relationships between bone size and body mass can thus be explained (Jungers 1985). Furthermore, weight-bearing bones (e.g., vertebrae, calcaneus) or weight-bearing aspects of long bones (i.e., proximal ends) gain their structural stability through a meshwork of interconnected trabeculae. Such an arrangement ensures maximum strength while at the same time minimizing weight; unsurprisingly 70% of all the bone is thus trabecular bone (Huiskes 2000). In order to optimize the functional adaptations of bone, trabeculae tend to align along the principal stress trajectories (Biewener et al. 1996; Gefen and Seliktar 2004). While these general relationships appear valid, studies have questioned whether bone is indeed as plastic, i.e., responsive to loading conditions, as previously thought, especially after adolescence (for recent review see Pearson and Lieberman 2004).

In an innovative comparative study, Ruff et al. (1994) investigated the response of bone remodeling during different stages of ontogeny. They found that increased mechanical loading prior to (or during) adolescence leads to an increase of cortical bone thickness due to periosteal expansion. Conversely, increased loading during the later stages of development results in endosteal contraction with external diameters remaining relatively unaltered (Ruff et al.
Furthermore, cortical bone responds systemically to increased activity levels during ontogeny, even in the absence of direct loading (Lieberman 1996). Increase in bone length, on the other hand, is largely stimulated through the effects of growth hormone at the growth plates and via muscle action (Vogl et al. 1993). Thus, in summary, it would seem that physical activity during development, i.e., during adolescence in particular, will have the greatest effect on bone remodeling, whereas activity levels during adulthood will result in only minor changes. Reconstruction of population-specific activity levels from adult bone geometry alone could therefore be misleading (Macho 1990, 1991; Ruff et al. 1993) and results need to be interpreted with caution. Similarly, trabecular alignment within bones is apparently developed relatively early during development (Biewener et al. 1996; Tanck et al. 2001) and is the result of differential growth in areas where strengthening is needed and resorption, especially later in life, where it is not (Biewener et al. 1996; Tanck et al. 2001). However, and unlike cortical bone which will only remodel in adulthood, trabeculae retain some potential to model throughout life (Frost 1990; Kobayashi et al. 2003). This is an exciting aspect of trabecular bone, and anthropological studies have already begun to exploit the functional information contained within cancellous bone in extant primates and extinct hominins (Macchiarelli et al. 1999; Fajardo and Müller 2001; Fajardo et al. 2002). While trabecular orientation may prove indicative of the loading directions experienced during life, much elucidation of phylogenetic constraints may come from analyses of carpals and tarsals.

Carpals and tarsals lack epiphyseal growth plate and, with some rare exceptions, also lack muscle attachments (Lewis 1989). Prior to ossification, these bones exist as cartilaginous models, resembling the future bone shapes. While the articular cartilages have a germinal layer, articular cartilage chondrocytes are much less responsive to growth factors than those of epiphyseal plates (Moss-Salentijn 1992). Owing to the absence of both growth plates and muscle attachments, carpals and tarsals therefore seem less influenced by changes in growth hormone (unlike long bones and cortical thickness of the skull). Rather their size and shape is apparently more strongly determined by intrinsic mechanisms than long bones (Bryant and Simpson 1984; Dainton and Macho 1999a, b). If correct, the mosaic nature of morphological changes seen in the hominin fossil record can be explained. For example, Australopithecus anamensis exhibits unequivocal bipedal traits in its lower limb morphology, but the carpal morphology resembles that of the chimpanzees (Leakey et al. 1998; Ward et al. 2001). Although it is recognized that this may indicate retained adaptations to arboreal life (Leakey et al. 1998; Ward et al. 2001), based on the results of the studies outlined earlier, it is not unreasonable to suggest that changes in wrist bone morphologies may lag behind those of long bones due to phylogenetic constraints.
26.3 Determination of functional adaptations

Adaptations are traits which enhance the fitness of the species and have arisen over evolutionary time as a result of natural selection for present biological roles (Rose and Lauder, 1996). Inferring the functional adaptations is not trivial, however, even when the traits under investigation do not constitute evolutionary novelties. Comparative analyses based on analogy with extant taxa assume that structure and function are intricately linked, but this is seldom the case (Lauder 1997; see later). Furthermore, most biological structures have evolved to fulfill more than one function. The role of the primate hand in locomotion and manipulation (Fleagle 1999) and the human orofacial skeleton in mastication and communication (Shiller et al. 2002) are only two of many examples.

From a phylogenetic perspective, traits which are advantageous and enhance the fitness of the species may in fact have evolved for a different purpose or they could initially have been the result of random genetic drift, pleiotropy, or correlation with other structures (Gould and Vrba 1982). In order to affirm that evolution has selected for a certain trait, it is imperative that extant analogs exist and that the function is similar in all living species. Inferences about functional adaptations thus formulated should then be supported by biomechanical analyses (Thomason 1997). Additionally, the first appearance of the feature must be found to coincide with (and be supported by) ecological and environmental evidence, for which the feature and its functional adaptation had apparently been selected (Lauder 1982; Anthony and Kay 1993; van Valkenburgh 1994). Given the latter premise, it is not surprising that hominin morphology is increasingly interpreted within the ecological and environmental settings of these species (Vrba et al. 1995; Bromage and Schrenk 1999; Leakey et al. 2001; Bonnefille et al. 2004).

It is evident that determination of whether or not a morphological feature constitutes a functional adaptation to certain environmental conditions is not straightforward, as the fossil record is incomplete, experimental data on extant species are scarce, and there is much to learn about the environment in which early hominins evolved (Agusti Volume 2 Chapter 6; Vrba Volume 3 Chapter 4). Conversely, ascertainment of the kinematic possibilities of joint surfaces (Tocheri et al. 2003) on the one hand, and the properties of morphological structures of bone and teeth (Macho et al. 2005), on the other, may provide the necessary prerequisites for more sophisticated functional analyses and more plausible behavioral interpretations.

Over the last decade, engineering tools such as finite element stress analyses (FESA) have become incorporated in the paleoanthropological tool-kit (Ross 2005). FESA is a numerical modeling technique that examines the deformation
of a model composed of a meshwork of elements with given material properties. This technique is particularly useful for an assessment of the internal mechanical behavior of structures that cannot be tested directly (e.g., through strain gauges). The behavior of bone (Korioth et al. 1992) and teeth (Spears and Macho 1998; Macho and Spears 1999) can thus be tested noninvasively; this makes this technique particularly suited for the analyses of valuable fossil remains. Recent advances in technology have further facilitated application of this method to the study of stress flow within trabeculae (van Rietbergen et al. 1995; Gefen and Seliktar 2004). This promises to open exciting new prospects for the study of fossil hominins and the functional adaptations of their morphological remains.

As regards dental remains, FESA has already proved useful in determining the mechanical adaptations of intact teeth and has confirmed the importance of understanding the interplay between tooth loads and tooth behavior when assessing their functional morphologies (Spears and Macho 1998; Macho and Spears 1999). Specifically, the systematic results from molars of modern humans and, to a lesser extent, Pan and Pongo imply a modified mortar-and-pestle system of mastication in hominoids, whereby buccal cusps of mandibular molars may act as pestles and the occlusal basin of maxillary molars apparently provide the basin against which the food is crushed (Spears and Macho 1998; Macho and Spears 1999). Despite the limitations of the models, their usefulness for paleoanthropology is clearly evident, although the application of FESA to fossil remains provides additional challenges as the findings cannot be validated against behavioral data (Macho et al. 2005; see also in a later section).

### 26.4 Determination of behavior

This is probably the most difficult and contentious aspect of anthropological enquiry. Generally inadequate correspondence between morphology, performance, and behavior has already been highlighted (Lauder 1997). The tools available to make behavioral inferences are varied but largely rest on comparative approaches aiming to deduce the biological role of morphology (bone and tooth size and shape, muscle markings, etc.) from modern analogs. Yet, fossil species are unique and may not have modern analogs.

Over the last few years, FESA models have become more elaborate (Ross 2005) with the ultimate goal of determining the masticatory performance in extinct species. As the limitations of FESA are numerous, other techniques are more likely to make a contribution to our understanding of the functioning of complex systems. Specifically, the boom in experimental research on different aspects of biomechanics in primates (Demes et al. 1999; Hylander et al. 2000;
Ravosa et al. 2000; Schmitt and Hanna 2004; Franz et al. 2005), the application of biomechanical principles to the primate skeleton (Preuschoft 1973; Weishampel 1993), new analytical techniques (Osborn 1996; Langenbach and Hannam 1999; Koolstra and van Eijden 2001; Langenbach et al. 2002; Nagano et al. 2005), and a better, although still very incomplete, understanding of the complex networks in motor control (Ostry and Feldman 2003) have led to the application of sophisticated dynamic modeling approaches to the locomotor system (Nagano et al. 2005) and the masticatory apparatus (Langenbach et al. 2002). In extant species, such modeling approaches help to make predictions about structures that are inaccessible to direct experimentation. For example, EMG data on the pterygoid muscle cannot be obtained in vivo, except in exceptional circumstances and with great difficulty (Huang et al. 2005). Similarly, the loading conditions within the temporomandibular joint during normal mastication are inaccessible to direct measurements. As such, dynamic models are designed to formulate hypotheses about the biomechanical behavior of functional units. Although this is also true for the analyses of fossil remains, the assumptions made and limitations necessary to create the dynamic models weigh even more heavily.

First, hominin fossils are fragmentary and associated partial skeletons are extremely rare (Johanson et al. 1978, 1982, 1987; Walker and Leakey 1993; Toussaint et al. 2003). Reconstruction of the bony elements must therefore rely on the experience of the morphologist working with comparative material and/or composite constructs of functional units (Alba et al. 2003). Inherent in this latter approach is the possibility that morphological differences between individuals, as well as temporal changes in morphology, will become obscured. Second, the soft tissue and its properties can never be known, yet they must be inputted into sophisticated dynamic models. In light of recent research, which demonstrated the species-specific nature of muscle architecture (Taylor and Vinyard 2004), assumptions often made with regard to muscle properties in extinct species may be questionable. Ontogenetic changes in muscle fiber properties (Shida et al. 2005) are another confounding factor when modeling juvenile specimens and when reconstructing the life histories of extinct species. Third, the musculo-neurological network provides a feedback mechanism for movement and hence fine-tunes the functioning of complex systems (Ostry and Feldman, 2003; Malfait and Ostry 2004), but it cannot be known (and can never be tested) in extinct species. Although comparative experimental studies may ultimately determine similarities between closely related species in neural control, given the difficulties in setting up and executing such experiments, these data are unlikely to become available in the near future. What is more, even if these shortcomings could be overcome, there are other problems with which paleoanthropologists aiming to reconstruct the behavior of extinct species are faced.
The fact that a species was capable of certain functions and behaviors does not necessarily imply that it habitually did so. Both modeling and biomechanical analyses can only determine the boundary conditions of morphological structures and infer their capabilities. A distinction must be made between what a species could do and what it did do. As a case in point, a FESA study on A. anamensis dental microstructure suggests that this hominin probably dissipated higher loads during mastication than any of the extant hominoids studied (Macho et al. 2005). Whether A. anamensis habitually ate hard and tough foods or whether it was adapted to cope with the vicissitudes of annual food shortage associated with a seasonal habitat (Macho et al. 2003b) remains uncertain. It is conceivable that deterioration of the quality of food for a short period during the annual cycle could have equally selected for morphological changes as much as would a habitual shift in diet and the exploitation of a new dietary niche. Interpretation is further hampered by the fact that the effects of partitioning of the environment among sympatric species and its limiting effects on a species’ behavioral repertoire cannot be appraised from the fossil record. Among hominoids, for example, sympatric Pan and Gorilla feed on the same fruits during the fruiting season, but food selection changes more dramatically among gorillas than chimpanzees during the dry season (Kuroda et al. 1996; Yamagiwa et al. 1996). This may similarly have been the case for sympatric hominins: the overlap in morphological features and life histories between Homo and Paranthropus in East Africa (Wood and Strait 2004) could thus be explained.

Finally, there are different ways of achieving the same end-result. Marzke has devoted her life’s work to understanding the morphological correlates between hand morphology and tool use, with some encouraging results (Marzke 1971, 1997; Marzke and Marzke 1987, 2000; Marzke et al. 1992). In a recent collaborative study (Tocheri et al. 2003), she used morphometric techniques to analyze the orientation of joint surfaces of wrist bones (i.e., trapezium) in A. afarensis and Homo habilis, as well as in extant hominoids. Unexpectedly, A. afarensis appears to be similar to modern humans in joint orientation and morphology, whereas H. habilis falls within the Gorilla range. The kinematic differences among wrist bones would have affected the functional capabilities of the hands of these two species. This finding is apparently in conflict with archeological evidence of stone tool manufacture in H. habilis and led the authors to entertain the possibility that H. habilis may have manipulated the stones in ways not found in modern analogs. This need not be reflected in the end-product, i.e., stone tools. Such propositions are not only reasonable but likely and are strengthened by recent behavioral studies, which have demonstrated tool manufacture by various animals in the wild (Boesch and Boesch 1990; Emery and Clayton 2004), irrespective of morphological differences. Phrased differently, the inference of behavior from
morphology, such as tool manufacture from hand and wrist bones, seems more remote than ever.

26.5 Conclusions

Fossil remains of hard tissue, such as teeth and bones, provide a wealth of information for the evolutionary biologist aiming to reconstruct the phylogenetic history and functional adaptations of extinct species. Unfortunately, disentangling these various aspects is not trivial and requires that paleoanthropologists employ a number of analytical tools, draw on information obtained in other disciplines (i.e., developmental and experimental studies), and collaborate with researchers in other areas (e.g., engineers). Regardless, problems will remain as many of the techniques have inherent limitations and are built on assumptions that cannot be tested using the fossil record. Nevertheless, given the increasingly multi- and interdisciplinary nature of paleoanthropological research, new and exciting (as well as partially testable) hypotheses are being generated at a faster rate than ever before. This makes paleoanthropology a dynamic and challenging area of research.

Abstract

Reconstruction plays a crucial part in working with fossils. A new aspect of reconstruction has been introduced by recent advances in 3D technology: the digital reconstruction of real objects. With the assistance of various computer-based techniques, such as surface scanning or computed tomography (CT), digital object data can be acquired and processed. Computer-based methods have in common that they are nondestructive as the handling of the fossil takes place within the computerized environment only. This aspect alone is of great advantage in comparison to conventional reconstruction and measuring techniques. Additionally, when reconstructing a fossil digitally, all steps are comprehensible and can be reversed.

With the assistance of a new methodological inventory, much additional information can now be derived from fossil specimens. Medical imaging techniques enable the visualization of internal morphological structures, formerly inaccessible for morphometric and biomechanical analysis. Furthermore, quantitative computer-based measurements are reproducible, as all measuring points on the digital objects can be saved.

This chapter gives a brief introduction to state-of-the-art techniques for 3D data acquisition and computer-based data analysis. Some applications in paleoanthropological research are presented to demonstrate that 3D technology has become an indispensable tool, complementing classical methods in physical anthropology.

27.1 Introduction

Reconstruction plays a crucial part in working with fossils. In a narrow sense, most fossils need to be reconstructed before the scientist can start to elicit information from the specimens, as they tend to be broken or distorted through
diagenetic processes. In a broader sense, not only the fossil itself needs to be reconstructed but also, as an ultimate aim, its place in evolution. Therefore, the function of specific morphological features, in combination with a paleoenvironmental approach, must be determined, in order to understand the role of an organism.

A new aspect of reconstruction has been introduced by recent advances in 3D technology: the digital reconstruction of real objects. With the assistance of various computer-based techniques, such as surface scanning or computed tomography (CT), digital object data can be acquired and processed. What computer-based methods have in common is that they are nondestructive. The handling of the fossil takes place within the computerized environment only, so that no actual damage to the original specimen will occur through physical contact. This aspect alone is of great advantage in comparison to conventional reconstruction and measuring techniques. When reconstructing a fossil digitally, all steps are comprehensible and can be reversed without damaging the specimen. Additionally, quantitative computer-based measurements are reproducible as all measuring points on the digital objects can be saved. Therefore, a comparison between measurements of different researchers should provide better results.

CT additionally reveals internal structures that have previously been inaccessible to scientific examination. Along with data acquisition techniques, new powerful computer-based analytical tools have also been developed. Geometric morphometrics, which enables the quantification of shape, is one of the most promising approaches to investigating fossil morphology. Thereby, 3D technology and computer-based analysis have enormously helped to enhance our knowledge of functional morphology of extant and extinct hominids.

This chapter will provide a brief introduction to state-of-the-art techniques for 3D data acquisition (Figure 27.1) and computer-based data analysis. It will point out the great impact those techniques have on paleoanthropological research. With the assistance of a new methodological inventory, much additional information can now be derived from fossil specimens. And it is crucial to gather as much information as possible from fossils due to their rarity and incompleteness. For these reasons, 3D technology has become an indispensable tool, complementing classical methods in physical anthropology. This is most important in the visualization of internal morphological structures, in morphometric and biomechanical analysis, and in the reconstruction of fragmented fossils. With the assistance of some exemplary applications, the significance of 3D technology for paleoanthropology will be elucidated further.
27.2 Medical imaging techniques

Medical imaging techniques have always been employed in paleontological and paleoanthropological research. Only a few years after X-rays were discovered by W.C. Röntgen in November 1895, this new technique was introduced to paleoanthropology by Gorjanovic-Kramberger (1902, 1906) to study the Krapina Neanderthals. X-ray technology offered the possibility to see the internal structure of rare and valuable specimens in a nondestructive way for the first time.

27.2.1 CT

The development of CT in the 1970s (Hounsfield 1972, 1973) provided 2D cross-sectional images that did not suffer from the superimposition of structures as in conventional radiography (Wind and Zonneveld 1985). This technique was applied to paleontological and paleoanthropological studies in the 1980s (Conroy and Vannier 1984, 1985; Wind 1984; Zonneveld and Wind 1985).

CT is an X-ray–based imaging technology that has in the meantime become a standard tool in noninvasive medical diagnosis and the method of choice for investigating skeletal morphology (see also Lange et al. 1988; Jend and Tödt 1989;
A medical CT scanner consists of an X-ray source which emanates a fan beam that tangentially scans a slice of an object and an opposite array of detectors or a detector ring. The X-ray source rotates around a patient or specimen table while the detectors measure the attenuation of the X-rays from multiple directions in the scan plane. Attenuation is dependent on the density properties of the object and is converted into an electronic signal by the detectors. If measured from different directions, the spatial distribution of the attenuation data of one slice can be calculated (see Kak and Slaney 1999 for the mathematical background). These data are then mapped as a cross-sectional gray-scale image depicting different material densities, or attenuation coefficients, with black representing the lowest and white the highest density. Attenuation coefficients are calculated for each voxel (volume element, see later) from the detector measurements and expressed as CT numbers. The CT number scale is given in Hounsfield units (HU) and is defined by a value of −1000 HU for air, and 0 HU for water (Lange et al. 1988; Jend and Tödt 1989; Hoxter and Schenz 1991; Wegener et al. 1992). Being a digital image, the cross-sectional image of a single CT scan consists of a limited number of pixels (picture elements). Each pixel actually represents a voxel as the image depicts a slice of a given thickness. The pixel is allocated the gray value of the average attenuation coefficient in the voxel. The spatial resolution in the plane of the scan is determined by X-ray beam geometry and pixel size. Pixel size depends on the scanner’s pixel matrix and the field of view and can at best be approximately 0.3–0.5 mm in current medical scanners. Perpendicular to the plane, the spatial resolution is significantly poorer as it is determined by the minimum slice thickness, which is currently about 1.0–1.5 mm in high-resolution medical CT (Spoor et al. 2000a). A stack of cross-sectional images is obtained by moving the table so that CT images of contiguous or overlapping slices can be made. In this way, the whole volume of an anatomical feature can be depicted.

A much higher spatial resolution and thinner slice thickness can be obtained by micro-CT scanners. Some of those scanners work comparably to medical CT scanners. Others use an image-intensifier and a frame grabber with video camera to record radiographs in a great number of directions and calculate a 3D volume of CT numbers therefrom. These scanners were originally developed for industrial purposes and not for scanning living organisms. Therefore, they usually have a stationary X-ray source with a rotating object. The spatial resolution and slice thickness can be between 1 and 200 μm, and it is possible to obtain isometric voxels, i.e., identical pixel size and slice thickness (Spoor et al. 2000a). The scan time
with micro-CT is higher compared to medical CT scanners, as indeed are the costs for those custom-built systems. The results, however, especially in studying fossil morphology and small anatomical features compensate for these drawbacks.

Drawbacks occur in CT image quality when scanning fossils that may be difficult to overcome (see also Zonneveld and Wind 1985; Spoor and Zonneveld 1994; Spoor et al. 2000a; Zonneveld 2002). Problems arise because fossils are often highly mineralized and may be filled as well as surrounded with dense sedimentary matrix. If the density of the specimen is too great, or if its dimensions are too large, the X-rays cannot pass through sufficiently. This lack of detector signal results in “frozen noise” artifacts in the image, which are streaks of noise that obscure details. This problem often arises with matrix-filled, highly mineralized crania. To overcome this difficulty the signal must be increased, which can be achieved by increasing the slice thickness. This, however, reduces spatial resolution at the same time, and a best compromise must be found.

Medical CT scanners usually cover a CT number scale that is suitable for showing structures in a living organism. Fossilized bone and sedimentary matrix can have a density that is much higher than the scale’s maximum. Their attenuation coefficients are then assigned the highest possible CT number and corresponding gray value, which is white (white overflow). These overflow artifacts in images are white areas with no visible structural details. Older scanners do not assign the highest CT number to all attenuation coefficients above a maximum, but the CT number drops to the lowest value which is depicted as black after the maximum has been reached and rises up again from there (black overflow). In both cases, overflow artifacts make structural details in the affected area invisible. Additionally, the outline of the structure is altered and volume as well as surface measurements will yield incorrect results. To overcome overflow artifacts, the CT number scale of the CT scanner must be changed so that it covers the highest density of the fossil (Zonneveld and Wind 1985). Most scanners already have an extended CT number scale, while in others recalibration can solve the problem (Spoor and Zonneveld 1994).

Artifacts through “beam hardening” are another drawback when scanning fossils. Beam hardening is the absorption of low-energy X-rays from the spectrum while passing through the specimen, so that the remaining beam becomes proportionally richer in high-energy photons (Kak and Slaney 1999). This occurs within all CT scanners and they are calibrated to compensate for beam hardening. As they are usually calibrated for scanning living organisms, however, more beam hardening may occur in scanning fossils. Recalibrating the CT scanner with, e.g., aluminum for the compression of the CT number scale is a solution (Zonneveld and Wind 1985; Spoor and Zonneveld 1994).
27.2.2 MRI

Magnetic resonance imaging (MRI) was also developed and applied to diagnostic imaging in the 1970s and 1980s (Lauterbur 1973; Mansfield et al. 1976; Mansfield and Pykett 1978; Edelstein et al. 1980; Steiner and Fiegler 1989). Its use in paleoanthropology is limited because it images soft tissue best and is therefore most applicable to specimens *in vivo*. It can, however, provide valuable information for actualistic studies concerning growth and development and is therefore considered briefly here.

MRI, like CT, produces cross-sectional images. However, this technique is not based on X-ray technology but rather maps the relative abundance of protons in the presence of a strong, static magnetic field. Using radio-frequency pulses, the protons are brought from equilibrium into a higher energy state. After the pulses stop, the protons begin to change back to their lower energy state, while emitting energy in doing so. This energy is received as a signal. The strength of the signal is proportional to proton concentration and is further characterized by the chemical and physical environment of the tissue (see Mansfield and Morris 1982; Steiner and Fiegler 1989; Kak and Slaney 1999; Spoor et al. 2000a, Vlaardingerbroek and den Boer 2003; Huettel et al. 2004 for further technical details).

As in CT, the MR signal is calculated for each voxel and its associated pixel and is depicted on a computer screen using a gray scale. Spatial resolution of medical MRI is about 0.7–1.0 mm with slice thickness being 1.0–3.0 mm. High-resolution MRI also exists with a spatial resolution of 156–300 μm and slice thickness of about 300–600 μm (Spoor et al. 2000a). Imaging times in high-resolution MRI are much longer, though, at about 24 h per specimen, so that artifacts in the images caused by movements can occur. Imaging contiguous or overlapping slices of a specific structure allows the mapping of the whole volume. As previously mentioned, hard tissue like mineralized bone, which is proton deficient, produces only a very weak signal and can therefore not be imaged properly. The surrounding soft tissues, like the brain or cartilage, however, emit a strong echo. Ossified tissue can nonetheless be visualized by MRI, as it is silhouetted against the depicted soft tissue.

27.2.3 3D Visualization

After having obtained a stack of contiguous 2D cross-sectional CT or MRI images, a digital 3D reconstruction of the specimen or parts thereof can be conducted using computer graphics techniques. If serial CT sections are examined
individually, even the experienced investigator may have problems in appreciating the 3D morphology of a region of interest. The first attempts at 3D imaging based on a volume of CT slices occurred in the early 1980s (Vannier et al. 1985; Conroy and Vannier 1986; Vannier and Conroy 1989a, b; Hemmy et al. 1994). Today, this technique is commonly applied (e.g., Zollikofer et al. 1995, 1998; Rae and Koppe 2000, 2002; Gantt et al. 2003; Kono 2004).

The most common technique for reconstructing selected structures (e.g., the skull) in 3D is surface rendering. The first step, the extraction of selected tissues (e.g., bone) from the dataset, is called segmentation. This is mostly conducted by thresholding: choosing the range of density values of the selected tissue to be displayed and removing other CT numbers from the image. This procedure has to be carried out for each cross-sectional image. Thresholding sometimes does not provide satisfactory results, especially when, e.g., bone and adhering matrix have similar CT numbers and are therefore difficult to distinguish. Local differences in mineralization of fossil bone add to thresholding problems. Another difficulty is the definition of the threshold as CT numbers at the borderline between tissues (e.g., bone and air) may differ from the “typical” values due to the averaging of attenuation coefficients in each voxel/pixel (partial volume averaging) (Spoor et al. 2000a, b). If the chosen threshold range is too small, parts at the outline of the chosen structure may be removed. If it is too large, the neighboring tissue will not be totally removed. Interactive segmentation in which the scientist is able to mark regions of interest manually can improve segmentation results. Edge detection and region growing software tools may also help (Spoor et al. 2000a). In the case of fossilized bone and adhering matrix, it is sometimes still impossible for the experienced observer to distinguish these two tissues, even visually. Prossinger et al. (2003) introduced a filter that helps in distinguishing bone from matrix and enables segmentation. Further progress will hopefully facilitate this very time-consuming task of segmentation.

After removing nonrelevant tissue from the slices, the images are combined along the border-lines of selected structures so that the structure surface can be viewed three-dimensionally. Subsequently, a surface model can be rendered by triangulation of the segmented object. Sequentially stacked slices sometimes result in uneven surfaces of the digital model. Smoothing algorithms can be applied to enhance the realistic appearance of the object. Computer graphics techniques in general have improved significantly, resulting in increasingly realistic images. The accuracy of the digital reconstructions, however, is limited by the spatial resolution in the scan plane, the slice thickness, and the slice increment (Spoor et al. 2000b).

Shadowing the 3D images by virtual light sources produces the effect of spatial depth and facilitates examination of the digital model. Viewing the
internal structures of the digital reconstruction of the specimen is enabled by merely cutting away or making translucent overlying structures of the model.

27.2.4 Medical imaging techniques in paleoanthropology

One application of CT data has already been demonstrated: the computer-based preparation of fossils. Fossils may be filled with or enclosed in sedimentary matrix so that physical preparation might destroy the precious fossil or at least parts thereof. Internal structures cannot easily be accessed nondestructively, or the position of the fossil parts within the stony matrix cannot be estimated reliably. In a different scenario, a fossil may have already been physically prepared and also reassembled previously and is now fixed with plaster and glue, but the reconstruction is debatable. In all these cases, it might be desirable to isolate the fossil parts and to reconstruct the specimen (anew) without damaging the fossil. Through digital preparation, matrix and fillings as well as formerly applied artificial reconstruction material can be removed from the digital bone. As described previously, matrix and other material can be removed by thresholding during the segmentation process (Vannier et al. 1985; Conroy and Vannier 1986). Manually guided “electronic chisels” (Ponce de León 2002), semiautomatic software tools (Spoor et al. 2000a), or filter algorithms (Prossinger et al. 2003) can refine the preparation results. Some specimens that are too fragile to be physically prepared, or are filled with matrix that cannot be accessed without damaging the specimen, can now be investigated digitally (Spoor and Zonneveld 1999; Prossinger et al. 2003).

A good example for a fossil specimen that has been digitally dis- and reassembled is Le Moustier 1. The adolescent Neanderthal skull was physically reconstructed several times, the last time in 1925 by Weinert, and was partly disassembled during the late 1960s (Thompson and Illehrhaus 1998). Different workers have applied electronic techniques to reconstruct the skull digitally from serial CT scans (Thompson and Illehrhaus 1998; Ponce de León and Zollikofer 1999; Ponce de León 2002; Thompson et al. 2002). Plaster, glue, and other matrix, which was hard to differentiate from the fossil material by mere vision, could be removed from CT images. All bony fragments were able to be isolated and reassembled digitally (Figure 27.2), and it was then possible to investigate the specimen again in the light of current knowledge (Ullrich 2005).

Computer-based reconstruction of specimens like Le Moustier 1 may also be necessary because the fossil fragments are distorted by the taphonomic process they underwent (see Grupe Volume 1 Chapter 7). A physical reconstruction of a
fossil from deformed pieces must remain unsatisfactory as measurements that are taken on it in the end yield incorrect results. Strong bilateral asymmetries, e.g., indicate plastic distortions. Sometimes, CT analysis reveals internal deformations that have remained undetected previously as in the Steinheim cranium (Prossinger et al. 2003). Digital reconstruction can be very useful in solving this problem by computerized deformation of the fossil back to its original shape. Vannier et al. (1985) already mentioned the method of deforming skeletal parts of the computer model to visualize pathological pre- and postoperative conditions, and suggested it for digitally reconstructing deformed fossil skulls. In the meantime, the methods for plastic distortion of digital objects have improved enormously. Information about the in situ situation of the fossil is needed. The original shape can be obtained by applying reverse forces to the gravitational

Figure 27.2
Reconstruction of LeMoustier 1 from micro-CT scans. Fragments are differentially shaded. It should be noted that only the original bony parts were used for this reconstruction. Micro-CT scanning was done by B. Illerhaus at the BAM, Berlin, image processing and reconstruction were conducted by J.L. Thompson using the software AVS (courtesy of B. Illerhaus)
forces that caused the deformation (Zollikofer et al. 1998; Ponce de León and Zollikofer 1999; Ponce de León 2002; Thompson et al. 2002; Zollikofer 2002; Zollikofer and Ponce de León 2002). However, as not every diagenetic event that led to postmortem modifications can be fully assessed, the resulting shape still remains tentative, and the resulting reconstructions are sometimes hotly debated.

Taphonomic processes not only result in plastic deformation but also in fragmentation of the fossil and loss of skeletal parts. Fractured objects can be reconstructed digitally by joining the fragments in their original orientation. Assembling the pieces is usually a stepwise procedure and demands practical knowledge of skeletal anatomy. If teeth are present, occlusional relations can be used to match antagonistic teeth and bony fragments of upper and lower jaws (Thompson and Illerhaus 1998; Ponce de León 2002). The bony labyrinth serves as an “anatomical compass” to orient temporal and adjacent bones (Zollikofer et al. 1995, 1998). Other fragments are added and realigned piece by piece to allow the edges of the bone fragments to meet correctly (Thompson and Illerhaus 1998).

Missing parts can be completed by either mirroring existing pieces of the same specimen (Zollikofer and Ponce de León 1995) or by adding corresponding parts from similar specimens that can be scaled and deformed (Kalvin et al. 1995; Zollikofer et al. 1998; Weber et al. 2003; Neubauer et al. 2004).

In summary, one can say that the reconstruction of fossil specimens (in a narrow sense) has gained enormously by applying computer-based methods such as digital plastic deformation and mirroring. Another advantage of reconstructing a fossil digitally is that all steps are comprehensible and, most important, can be reversed anytime without damaging the specimen. Once a best solution for the reconstruction is found, the original specimen can be reconstructed physically, either by using the original parts or by means of rapid prototyping (see Section 27.4).

The fossil cannot only be reconstructed digitally. Computer-based analysis also provides a direct dataset for established as well as new means of investigating the specimen.

Determining the volume of the endocranial cavity from a stack of CT scans was one of the first applications the new technology offered which was used (Vannier et al. 1985; Conroy and Vannier 1986), and it is still one of the main concerns of CT investigations (Conroy et al. 1998, 2000; Weber et al. 1998; Recheis et al. 1999; Falk et al. 2000; Thompson et al. 2002; Neubauer et al. 2004). Cranial capacity, representing brain size, is measured as an important item of taxonomic classification. Measurement of other cranial cavities, like sinuses, to better understand their functional and phylogenetic significance is also possible nondestructively by using CT scans (Prossinger et al. 2000; Rae and Koppe 2000, 2002; Prossinger et al. 2003). Determination of the volume of hollow features can
either be carried out on single cross-sectional CT images that are measured individually or directly on the digital 3D reconstruction. For measuring the volume, in the former case, the 2D area of the region of interest in the image is measured and multiplied by slice thickness, and the measurements for all slices finally summed up (Conroy and Vannier 1985; Rae and Koppe 2000). To determine the volume in the latter case, an algorithm counts the number of voxels and multiplies by voxel size (Prossinger et al. 2003). To obtain a best estimate for brain size, some refined techniques can be applied to this simple calculation (Weber et al. 1998).

With the development of high resolution and micro-CT scanners, very small internal anatomical features are now possible to visualize. One of the most famous examples for this kind of application is the investigation of the bony labyrinth. This is located inside the petrous part of the temporal bone and is thereby only accessible nondestructively by applying CT. It houses the hearing organ as well as the sense organs for the perception of movement and spatial orientation. Zonneveld and Wind (1985) showed that it is possible to image the labyrinth of fossil hominids with a series of high-resolution CT scans. They hoped to be able to obtain information about the physical properties of hearing and speech of fossil species by reconstructing the middle and inner ear. At the same time, they realized that the orientation of the semicircular canals might be used as an indicator of locomotor behavior (Wind and Zonneveld 1985). Spoor and colleagues followed this approach to determine the emergence of bipedalism in hominid evolution (Spoor and Zonneveld 1994, 1998; Spoor et al. 1994, 1996). They found that canal size and locomotor behavior were correlated and humans had larger anterior and posterior semicircular canals and a smaller lateral canal than other extant primates (Spoor and Zonneveld 1998). Among fossil hominids, the australopithecines show apelike proportions, while *Homo erectus* is the earliest species to have humanlike semicircular canal morphology. This is interpreted as being indicative of habitual bipedalism in *H. erectus* and facultative bipedalism in australopithecines. The similar proportions of semicircular canals in the great apes are considered the ancestral hominid condition so that labyrinthine morphology can provide information about locomotor behavior as well as phylogeny in hominid evolution. The Neanderthal bony labyrinth has a derived morphology that allows taxonomic specimen identification (Hublin et al. 1996; Spoor et al. 2003) (Figure 27.3). This is also possible for subadult individuals as the labyrinth already possesses its adult morphology at the time of birth (Spoor and Zonneveld 1998).

A different application in which the small size and fossilized nature of objects make special demands on the method of investigation is the determination of enamel thickness. Enamel thickness as an important functional and taxonomic
character has been the center of many investigations since the 1970s. Most studies have used sectioned teeth (Gantt 1976; Molnar and Gantt 1977; Martin 1985; Shellis et al. 1998; Ulhaas et al. 1999; Smith et al. 2003), which has considerably limited the number of specimens investigated, especially of fossils. Conventional radiography (Sperber 1985; Molnar et al. 1993; Smith and Zilberman 1994) as well as medical CT (Conroy 1991; Grine 1991; Macho and Thackeray 1992) have been employed to measure enamel thickness nondestructively with controversial results. Only high-resolution CT yielded satisfactory results (Spoor et al. 1993; Schwartz et al. 1998). The extremely high density of dental enamel and the small size of hominid teeth make it difficult to get exact measurements. Overflow artifacts (see Section 27.2.1) give the enamel cap a swollen appearance, which results in overestimation. Even in early high-resolution CT, with slice thickness of 1.5 mm and using overlapping scans, exact measurements below a critical distance were not possible due to still insufficient spatial resolution (Spoor et al. 1993). Current micro-CT scanners that are capable of a slice thickness of between 50 and 80 microns allow exact measurements of enamel thickness (Gantt et al. 2003; Kono 2004; Olejniczak and Grine in press) (Figure 27.4). Additionally, not only linear and area measurements in a fixed plane but also enamel distribution and volume can be measured using 3D reconstructions of the tooth crown. This technology therefore at last allows the nondestructive investigation of enamel thickness of fossil teeth. New insights into functional and phylogenetic implications of enamel thickness can also be expected by employing new 3D parameters. Due to the noninvasiveness and the good visualization of small features by high-resolution and micro-CT, other dental characters can now be studied as well, e.g., tooth root morphology (Kupczik et al. 2003).
MRI, as mentioned before, has a limited use for paleoanthropology as it can mostly visualize soft tissue. However, MRI is the method of choice for ontogenetic analyses (Bookstein et al. 2003) or studies of brain development with respect to phylogeny (Semendeferi et al. 1997; Semendeferi and Damasio 2000; Jeffery and Spoor 2002).

A different application of MRI in paleoanthropology is its use in soft-tissue reconstruction. The MRI image of a human head contains information about the depth of soft tissue that covers the skull. For facial reconstructions, the digital image of muscles, fat, skin, etc. overlying the facial skeleton instead of statistical
information of tissue depths can be used to reconstruct a face over a given skull. This kind of reconstruction has no immediate scientific value. But it is a means for getting realistic soft-tissue reconstructions of fossil hominids for museum exhibitions or schools.

### 27.3 Surface data

Many computer-based applications in paleoanthropology currently use digital data that have been acquired by CT scanning. Even though CT imaging offers much information about the internal morphology of the structures of interest, the data acquisition process is expensive in every regard. It can be long and tedious, the data volume that has to be stored is large, and the costs are relatively high, given the possibility to use a good CT scanner. If only the surface of an object is to be measured, however, several means for surface data acquisition exist (Dean 1996; Petrov et al. 1998; Beraldin et al. 2000), which serve the purpose well or even better than surface reconstructions from serial CT scans.

#### 27.3.1 Surface scanning

Several techniques have been developed to capture 3D surface information. These divide into optical and nonoptical, contact and noncontact, and active and passive sensing methods (Breuckmann 1993; Petrov et al. 1998; Beraldin et al. 2000; Godin et al. 2002; Zhang et al. 2002). Optical noncontact techniques ensure damage free data acquisition. While passive techniques operate under ambient lighting conditions and use natural features on the surface of an object to reconstruct it in 3D, active methods create features on the surface by controlled projection of light. Therefore, active techniques can be applied to a broader range of objects with fewer restrictions to surface texture and lighting. For scanning small and midsize objects and short measurement ranges up to a few meters, active optical triangulation systems are the most appropriate. Meanwhile, these systems provide photorealistic representations of shape and texture with reasonable speed (Figure 27.5).

Optical triangulation systems either use laser light or pattern projection. Triangulation scanners generally consist of a projector that either projects a laser beam or a grid pattern onto the object and one or more digital cameras. The light is projected from a known position in a known direction. In laser scanning systems, the direction of the returning light is measured by an angle sensor. With a fixed distance between projector and angle sensor, the known projection
angle, and the measured angle of the returning light, the position of the illuminated point can be calculated with regard to the system, according to the rules of triangulation. In systems using pattern projection, camera and projector are arranged in a fixed distance and angle to each other. The camera captures grid patterns on a target surface. Many patterns are known as “codes” (e.g., Gray code) and are meant to uniquely express light directions. If the surface is flat, the lines of the pattern appear straight and undeformed. Any surface features result in changes of the projected pattern. The lines will appear curved, bent, or otherwise deformed. Knowing the projection angle of the pattern, triangulation formulas as well as other mathematical techniques can be applied to calculate the profile of the surface (Beraldin et al. 2000; Godin et al. 2002; Zhang et al. 2002).

To obtain data on the whole object, the object has to be scanned in different views. To capture the whole surface, there is either a rotating specimen table or the light source rotates around the object. In some mobile systems, the scanner has to be manually moved around the object. Each view results in a 3D point

Figure 27.5
Reconstruction of H. rudolfensis mandible UR 501 from Malawi from surface scans. Fossil specimen is originally fragmented in three pieces. Fragments were scanned with a Breuckmann optoTop® scanner. Image processing and reconstruction was done with software Polyworks® (courtesy of F. Schrenk)
cloud. To visualize the complete surface, point clouds of the different views have to be matched and merged. Finally, a 3D point-cloud results that represents the complete surface of the object. Computer graphic techniques can again be used for surface rendering.

Color texture reconstruction of the digital model can be achieved by different methods. Color images of the object can be mapped on the 3D model surface using perspective projection. The quality of the result depends on the color image quality and the integration of images from different views that usually show slight differences in color and lighting. For laser scanning approaches, one solution is the use of a polychromatic laser so that color information of the illuminated spot can be measured directly. However, this technique requires scanning in very high resolution and is therefore not appropriate for scanning very large objects (Blais et al. 2003).

Optical-scanning systems have some limitations, though. Because the camera has to discern the light that is projected on the object, very dark or reflective surfaces and transparent media make it difficult to get good scanning results. Deep cavities or surfaces that are covered by other structures result in missing values as the projected light does not reach these object areas. Coating the specimen surface with matt and light powder, using different lighting conditions and scanning the object from various angles, however, enables the complete recording of most specimens.

One major advantage of laser-scanning systems is that the laser light can be easily filtered out from the ambient illumination so that they can be operated in daylight conditions. Pattern projection systems rather need dark surroundings as the grid pattern cannot be captured unambiguously by the camera in too bright lighting conditions.

Accuracy and resolution of both pattern projection and laser systems are reasonable. The main drawback in using laser light is speckle noise. Speckle is produced when a rough surface is illuminated with coherent laser light. Speckle appears as grains attached to a surface and results in measurement uncertainty. However, meanwhile special filters can reduce speckle noise and thereby enhance accuracy up to 0.01 mm. Resolution of laser optical triangulation is limited by the diffraction of the laser light. Usually, a resolution of 0.05–0.01 mm can be achieved. In pattern projection, using one grid code alone limits measurement resolution considerably. However, combining a code pattern with a phase-shift approach results in theoretically infinitely high resolution. In practice, resolution is limited by electronic noise and errors due to quantization of gray levels in the intensity image (Beraldin et al. 2000) and is comparable to laser-scanning systems. However, accuracy and resolution actually always depend on the object surface and texture.
27.3.2 Surface scanning in paleoanthropology

Surface scanning has been introduced to paleoanthropological studies only recently. Laser scanning was employed by Aiello et al. (1998) and Wood et al. (1998) for the investigation of joint surfaces of fossil limb bones. The aim of these studies was to determine if isolated fossil bones could be attributed to one individual or at least one species. These authors, as well as Harcourt-Smith et al. (2004), who applied geometric morphometric methods (Section 27.3.4), were able to show that the congruence of reciprocal joint surfaces can be ascertained on the taxonomic level and that refined statistical methods will enable the identification of unassociated skeletal elements of individuals.

Small objects like teeth can also be digitized by surface scanning. Ungar and colleagues (Ungar and Williamson 2000; M’Kirera and Ungar 2003; Ungar and M’Kirera 2003; Ungar et al. 2002) recorded hominoid molar surfaces with the help of a laser scanner and applied geographic information systems (GIS) to model, characterize, and compare tooth surfaces as landscapes. In a different approach, Kullmer et al. (2002, 2004) and Ulhaas et al. (in press) used pattern projection scanning to obtain digital models of hominid and other primate teeth. Both approaches aim at a topographic analysis of occlusal relief. The application of 3D methods for the analysis of tooth surfaces allows for the inclusion of new measurements that quantitatively record morphological traits that could be described only qualitatively before. Molar surfaces are measured and compared with regard to such features as surface area, basin volume, occlusal relief, and cusp slopes. Established measurements like tooth length can also be taken on the digital models and allow comparison with earlier investigations. The most important aspect of these 3D approaches is that it is now possible to include worn molars into analyses (Ungar and M’Kirera 2003; Ulhaas et al. 2004, in press). Many worn fossil molars that have never been used so far for functional and/or systematic analyses can now be studied with the assistance of a new methodological inventory.

Last but not the least, it is also possible to reconstruct fragmented fossils using 3D surface scans of the fragments, as can be seen on the example of the *H. rudolfensis* mandible UR 501 (Figure 27.5). As the use of surface-scanning techniques is quite new in paleoanthropology, many applications still wait to be explored.

27.3.3 Digitizing landmarks

Digitizers are systems for measuring 2D or 3D coordinates of landmark locations. Landmarks are homologous measuring points that can be reliably and repeatedly
located. The coordinate data can be recorded in different ways. First of all, a fixed coordinate system has to be defined in which the object is located. Therefore, the origin of the coordinate system and the endpoints of at least two axes are recorded. A digitizer usually consists of a stylus, which is used like a pen to mark the measuring points. The stylus can be part of a mechanical arm with several rotating joints. The positions of the joints allow the calculation of the landmark coordinates. Otherwise, 3D data can be recorded using interacting electromagnetic fields, the transmitter, and the receiver field. Each field is determined by a Cartesian coordinate system, formed by three antenna coils which are at right angles to one another. Whenever the transmitter coils are pulsed, a current is induced in each receiver antenna coil. The strength of the current is dependent on both the distance and the relative orientation of the transmitter and receiver coils. The resulting nine current values are used to calculate the 3D position of the landmark (Foley et al. 1990). Other systems use ultrasound waves to record the position of the stylus, or markers to mark the measuring points, while sensors or cameras determine the planes they lie in and thereby ascertain the 3D coordinates of the points (Foley et al. 1990). These latter systems are currently not used for anthropological applications. Although the electromagnetic system is especially prone to inaccuracies due to interferences by electric or metallic objects, such as the computer screen, the precision of measuring landmark data in anthropological applications is assessed as satisfactory (Baab et al. 2003; Marcus et al. 1997). Measurement accuracy of about 0.15 mm for the electromagnetic and 0.25 mm for the mechanical digitizer, however, is not sufficient to measure such objects as small primate teeth (Ungar and Williamson 2000).

27.3.4 Landmark data and geometric morphometrics

Landmark points can be joined linearly to portray the object surface. The closer the points are together, the finer will the surface representation be. Surface details though cannot be depicted and therefore cannot be studied using this method. Landmark data permit statistical analysis of biological form using either traditional morphometric methods (Sokal and Rohlf 1995) or the advantages of geometric morphometrics (Bookstein 1991; O’Higgins and Jones 1998; O’Higgins 2000; Richtsmeier et al. 2002). “Form” contains information about size and shape. While “size” is usually defined as a specific length, area, volume, or centroid and can be measured quantitatively, “shape” usually remains immeasurable and can only be described qualitatively. In geometric morphometrics,
variation in shape, defined as the spatial distribution of landmarks, can be analyzed independent of size by applying a set of morphometric tools. Among those are superimposition methods like Procrustes superposition (Rohlf and Slice 1990; Bookstein 1991), deformation methods like thin-plate splines (Bookstein 1991), and analyzing tools like Euclidean distance matrix analysis (EDMA) (Lele and Richtsmeier 1991), principal component analysis (PCA) (O’Higgins and Jones 1998), and relative warp analysis (Bookstein 1991). For further information about geometric morphometric methods, the reader is referred to Bookstein (1991); Bookstein et al. (1999, 2003); O’Higgins (2000); O’Higgins and Jones (1998); Richtsmeier et al. (2002); Rohlf and Slice (1990).

Landmark data can either be recorded on the original specimens using a digitizer or on the digital objects obtained by CT, MRI, or surface scanning. CT and MRI also offer the possibility of measuring internal landmarks. Anthropology has a long history of measuring biological form. Therefore, many applications exist that have used the opportunity to include new 3D landmarks and the methods of geometric morphometrics in the study of size and shape variation.

Harvati (2002, 2003a, b) investigated the morphological variation in cranial landmark configurations between Neanderthals and anatomically modern Homo. She showed that the morphological distance between these two groups is so large that the hypothesis that Neanderthals represent a subspecies of *H. sapiens* cannot be supported. Delson et al. (2001) used a comparative morphometric analysis based on landmarks to determine the systematic position of the Sabungmacan 3 *H. erectus*. Bookstein et al. (1999) were able to show substantial external cranial differences, but stable inner frontal bone morphology, between early and modern Homo.

Comparing not only different taxa but also different ontogenetic stages using geometric morphometrics allows a better understanding of growth patterns. Bookstein et al. (2003) and Mitteroecker et al. (2004a, b) were able to separate phylogenetic and ontogenetic processes that have an impact on cranial shape in great apes and humans. A comparison between Neanderthal and anatomically modern human immature crania (Ponce de León and Zollikofer 2001; Zollikofer and Ponce de León 2002) showed that morphological differences between these two groups appear very early during ontogeny, possibly prenatally, and are maintained during later development. The researchers conclude that morphological differences therefore have a genetic rather than an environmental background and that Neanderthals and modern humans should be separated at the species level.
27.4 Rapid prototyping

It was shown that many different analyses can be conducted on 3D digital models of fossil specimens. Nonetheless, is there sometimes a need for having a physical model to work with. It is easier to comprehend the spatial distribution of anatomical features when holding the specimen in one’s hands and turning it around, than if one is restricted to looking at a 2D image of a 3D model on the computer screen.

A means of getting the digitally reconstructed fossil into reality is rapid prototyping. Rapid prototyping technologies were originally developed for reverse engineering to get 3D hardcopies of digitally designed objects. The best-known technology is stereolithography (Ghezal and Stucki 1992; Bresenham et al. 1993; Zollikofer and Ponce de León 1995). With stereolithography, a 3D object is constructed in layers by computer-guided polymerization. For this purpose, the 3D digital model has to be converted into a special file format that allows cross-sectioning of the object into slices. Inside a container with photosensitive polymers, the slices are built consecutively by laser curing. A laser beam is guided by the computer across a liquid layer, according to the shape of a cross-section. Where the laser beam hits the liquid, the photopolymers harden. After one layer is completed, an elevator inside the container moves downward to submerge the object and to cover the hardened layer with a new layer of liquid of defined thickness, usually between 0.1 and 0.5 mm. The process continues until the object is completed. To prevent the stereolithographic model from sagging during the construction process, small supporting struts are added into the object that can be removed after the final hardening of the complete model. The accuracy of stereolithographic models is about 0.15 mm, while most of the error is due to inaccuracies from CT scanning and data processing.

The first stereolithographic model that was used for anthropological studies was the replica of the skull of the Tyrolean Ice Man (Seidler et al. 1992). The mummy was CT scanned and CT data used for the plastic reconstruction of the skull. The skull was built in two parts so that inner cranial details were directly visible. Access to internal parts as well as transparency of the reconstruction material enable direct visual comparison of traits like endocranial sinuses (Seidler et al. 1997). Zollikofer et al. (1995) used stereolithographic models to visually ascertain the correct alignment of anatomical elements during the digital reconstruction process. Stereolithography is also an alternative to casting fragile fossils. The specimen has to be surface-, MRI-, or CT scanned only once, which is a nondestructive procedure, as shown earlier. The 3D copy of a specimen obtained by stereolithography is as accurate as a conventional cast. Furthermore, multiple copies can be done without any loss of accuracy, as occurs with traditional
methods (Zollikofer et al. 1998). Additionally, just parts of the model that allow insight into the internal anatomy, or enlarged replicas of very small units, can be produced with this technique.

27.5 Conclusions and future prospects

It is clear that computer-based paleoanthropology has made much progress during the last two decades. Meanwhile, computer-based 3D technology has become a powerful means for paleoanthropological investigations. Data acquisition and analysis can be carried out nondestructively within a computerized environment. Fragile fossils or specimens that are embedded in sedimentary matrix and fragmented or deformed by taphonomic processes can be reconstructed with the new technologies. In reconstruction and analysis, all steps are reproducible and can be reversed without damaging the original specimen. With the assistance of a new methodological inventory, much additional information can now be derived from fossil specimens. The more information can be obtained, the better the reconstruction not only of the fossil itself but also our comprehension of its place in evolution.

Many fossils wait to be analyzed with the new techniques, so the amount of data that can be used in comparative studies will grow. Mobile systems are already available that allow surface scanners or high-resolution CT scanners to be brought to the fossils. This will further ensure a growing number of scanned specimens.

An increase in power and affordability of personal computers and the emergence of more appropriate software will convince more researchers to apply the new technologies. Imaging quality of surface scanners and in MRI is increasing, as well as commercial availability of micro-CT scanners. Furthermore, one of the disadvantages of the early systems has been overcome: universal formats that allow data exchange between different systems have been developed. Therefore, the call for setting up digital data archives and sharing data is not surprising (Spoor et al. 2000a; Weber 2001, 2002). Additionally, the combination of different data acquisition techniques, such as CT and surface scanning or CT and MRI, in multimodal applications is possible and will enhance analysis efficiency.

In future applications, not only static analysis but also studies of dynamic processes, like locomotion and mastication, will be conducted. The new kind of data and new measuring tools are not meant to replace traditional methods in physical anthropology but rather to complement them. Computer-based reconstruction technology has already become an indispensable tool in
paleoanthropological applications and will hopefully become a standard procedure in future investigations.

Acknowledgments

I would like to thank all of my colleagues who always tried to answer my questions concerning the amazing techniques available today. Special thanks to Bernhard Illerhaus, Anthony Olejniczak, Friedemann Schrenk, and Fred Spoor for providing figures to illustrate some applications.

28 Prospects and Pitfalls

Jean-Jacques Hublin

Abstract

Paleoanthropology is primarily rooted in the study of fossils and the analysis of sites. Dependence on these resources leads to challenges resulting from the difficulty in gaining access to scarce, precious, and sometimes overprotected materials, and from issues of control over field sites. The development of virtual paleoanthropology can sometimes be a way to partially solve the first problem. However on some occasions, the access to and utilization of numerical data has also become an issue of dispute. In parallel, recent advances in studies focusing on microstructures, isotopic composition, and paleogenetics require direct sampling of the fossils. The trend in paleoanthropology is to integrate approaches from different scientific fields, and this is especially visible in developmental sciences, genetics, and environmental studies. In the meantime, dealing with human evolution remains a sensitive topic, subject to clear ideological and religious biases. The interest of the media and of the public in this science does not always contribute to an objective approach to the questions. Finally, among other issues, the expansion of paleoanthropology studies in developing countries must contend with the decline of a colonial mode of thinking.

28.1 Introduction

In many respects, paleoanthropology is a paradoxical science. Although it addresses the oldest origins of humans, the discipline itself developed quite recently in the history of science. The first fossil hominid specimen on record, an immature Neandertal skull, was discovered in 1830 in Engis (Belgium). However, it was not until the end of the nineteenth century that certain fossil specimens were truly accepted by the majority of the scientific community as evidence for the evolutionary process that gave birth to our species. Although very significant discoveries occurred during the first half of the twentieth century and provided the basic framework for paleoanthropological studies, the last three decades of that century witnessed a spectacular increase in the available fossil record as well as in major advances in the knowledge of past environments and the chronological background of human evolution. Moreover, the birth of paleogenetics added
a new dimension to the analysis of relationships among fossil hominid species. The current state of the discipline results not only from methodological progress but also from a major effort of field research. For the public, the media, and students, it is always a matter of amazement and sometimes of criticism to realize that the field of paleoanthropology is such a changing terrain. If prediction, in science as in many other domains, is always a difficult exercise, it is even more challenging in this particular science, which is relatively newly born and still rapidly evolving.

Another distinctive aspect of paleoanthropology lies in the fact that the study of fossil specimens remains the core of the discipline. These are rare and precious objects. It is often emphasized that for the study of some extinct groups the specimens are fewer than the specialists who analyze them, and sometimes the competition is harsh. After an undefined period during which they remain under the relatively rigid control of individuals or groups responsible for publishing descriptions of them, they are usually curated in museums or other institutions. While the specimens are in their possession, the curating institution may also restrict access to the fossil specimens, emphasizing their conservation rather than their scientific study. On the one hand, there is therefore strong pressure to consult the fossil material, and on the other, growing restrictions that result from a multitude of reasons, ranging from the desire to maintain scientific monopoly to the legitimate policy of protection of fragile and valuable objects. In parallel, new techniques for the study of the specimens have been developed. However, these new methods sometimes resolve issues and sometimes generate new difficulties.

### 28.2 Virtual paleoanthropology

Since the 1980s, new techniques in medical and industrial imaging have revolutionized the fields of human paleontology and physical anthropology (Wind 1984; Wind and Zonneveld 1985; Zonneveld and Wind 1985) allowing the development of what has become commonly called as “virtual paleoanthropology.” The growing use of computed tomography as well as industrial imaging techniques (microtomography and laser scanners) has allowed the production of 3D images of fossil specimens. Combined with stereolithography and other techniques of 3D printing, these virtual representations have opened a number of new possibilities for the analysis of the specimens. Most notable among these are

- Virtual extraction and reconstruction (including correction of plastic distortions) (Kalvin et al. 1992; Zollikofer et al. 1995; Ponce de Leon and Zollikofer 1999)

• Precise quantitative analysis of inaccessible internal structure (including tiny structures, such as middle and inner ears, bony tables, vascular foramina, etc.) and their comparison with living references (Zonneveld et al. 1989; Hublin et al. 1996; Spoor et al. 1996)
• 3D morphometric analysis with the development of new mathematical tools (Harvati 2002)
• Modeling of ontogenetic processes, biomechanical properties, and of evolutionary changes themselves (Ponce de León and Zollikofer 2001; Mitteroecker et al. 2004)

Growing evidence suggests that, with increasing frequency in the future, the anatomy of fossil hominins will be systematically studied not from the specimens themselves but from virtual representations. Principal among all the new possibilities opened by virtual paleoanthropology is the reduced need to manipulate the real objects. Consequently, these techniques should be welcomed by many curators. However, they also raise new questions. One is related to the quality of the data. So far, the CT scanners that have been used to acquire the data are primarily those available in the medical environment. Although they evolve rapidly, machines of this type have their own limitations and are not specifically designed to explore fossilized specimens filled by dense sediments. The resolution of the 3D pictures produced in this way is far from satisfactory in many cases. Their quality could be greatly improved by the implementation of high-resolution industrial scanners designed for paleoanthropological use. Such machines have already been acquired by a handful of institutions in the USA, Japan, and Europe.

Among the pitfalls related to the development of virtual paleoanthropology is a shift from a situation where access to the fossil specimens was difficult to a situation where access to the numerical data is even more challenging. Curators are sometimes reluctant to allow repeated acquisitions of these numerical data, while the techniques and equipment evolve rapidly. Often, the data are monopolized by those who acquired them initially, and they are hard to upgrade. In the long term, databases may develop in some institutions and on the Internet. To date, however, the development of such databases has faced insuperable difficulties. The commercialization of some of these data by the institutions concerned or the simple trading of data between teams will remain, for sometime, the only alternative.

28.3 Into the matter of bone

In a somewhat opposite direction to virtual paleoanthropology, there are a number of other new approaches that have been developed in the fields of
human paleontology, physical anthropology, and archeology. Such techniques were initially based on rather invasive analyses of the specimens, inherited primarily from histology and geochemistry. However, with the rise of non- (or less) destructive methods, this field is rapidly expanding. In the future, study of the actual fossil remains will likely be reserved for the kinds of analyses that cannot be performed on virtual representations. At present, such analyses include, on the one hand, histological approaches mainly addressing bone and tooth microstructures and, on the other hand, chemical analyses addressing either geochronological or paleobiological questions.

Microstructural studies have developed mostly in the field of dental anthropology. The recognition of different types of incremental mineralized structures in the dentine and the enamel since the middle of the twentieth century has led to systematic analyses of their variation in extant and fossil primates (Dean 1987; Stringer et al. 1990; Lieberman 1993; Zhao et al. 2000; Dean et al. 2001; Martin et al. 2003; Schwartz et al. 2003; Smith et al. 2003). This development has been made possible by the improvement of technical equipment such as the scanning electron microscope, the confocal microscope, and computer-assisted microscopy for 3D visualization. The interest in these studies comes from the knowledge that microstructures could be the main, if not the only way, to assess life history in extinct species (FitzGerald 1998). This issue has been given increasing attention in an evolutionary perspective since the genetic bases of development have become better understood, and their importance for evolutionary changes better appreciated. Future research in this direction will certainly include extensive work on modern variability and more experiments to assess the biological significance of accretional microstructures and their relevance for calibrating the growth patterns of extinct species. Although it is possible to work on externally visible features, such as perikymata (Ramirez Rozzi and Bermudez de Castro 2004), a drawback of these methods is the necessity of slicing precious fossil specimens to analyze fine internal microstructures. However, the technique of thin slicing has greatly improved, and it is possible today to “rebuild” a specimen after analysis following minimal destruction of tissue. In the future, new techniques of imaging may also partly resolve this problem. Although, to date, it remains a very expensive technique, the use of synchrotron allows access to bone and tooth microstructures without destruction (Tafforeau et al. in press).

Chemical analyses of fossil specimens have been aimed at reconstructing paleobiological features and are mostly concerned with the extraction of organic molecules. Nonorganic chemical properties of the fossil remains are primarily relevant to the determination of their geological age and are marginally useful in addressing paleobiological issues. To date, DNA and collagen have been the main targets of the research on ancient biomolecules. Techniques based on the use of
Restriction enzymes have allowed the duplication and subsequent sequencing of tiny and rare fragments of DNA chains. So far, this work has been based primarily on the analysis of mitochondrial DNA, which is smaller and much more abundant than nuclear DNA. The sequencing of a fragment of mitochondrial DNA of the Feldhofer 1 (Neandertal) specimen in 1997 opened a new era of paleoanthropological studies (Krings et al. 1997). Future development of this research will involve the reconstruction of the entire sequence of the mitochondrial DNA in specimens such as Neandertals. With the development of new techniques, future work will also address the issue of nuclear DNA in fossil hominids. However, the natural degradation of DNA under given physical conditions imposes a chronological barrier that today seems oddly unsurpassable. Another serious problem in paleogenetic studies comes from the potential for contamination. Paradoxically, the DNA of modern and relatively recent humans remains very difficult to identify as genuine fossil DNA and to distinguish from subsequent contamination (Serre et al. 2004). Studies on the taphonomical processes affecting the deterioration of DNA chains in the archeological or geological deposits may provide an answer to this problem.

Isotopic composition of the mineral portion of hominid fossils has been used to assess biological issues. These studies face the difficult questions of the taphonomic transformation of the chemical composition of fossils in the geological layers (Radosevich 1993; Fabig and Herrmann 2002). Most researchers have thus focused on the more stable component of bone, the protein collagen (Schoeninger 1985; Ambrose 1986; Bocherens et al. 1991; Bocherens et al. 1997; Richards et al. 2000; Richards et al. 2001). Collagen has been the primary source for the analysis of stable isotopes such as oxygen, nitrogen, and carbon. These isotopes are fixed in the living tissues antemortem, either at an early stage of individual development (in the teeth, for example) or at some time before death. They are an essential source of information about the environment and the diet of individuals during their lifetimes. One constraint of these studies is that they are limited by the long-term preservation of collagen. One can expect that, as with the study of recent archeological series, such analyses in the future will bring unexpected knowledge on issues such as migration, seasonality, or even mating strategies among relatively ancient hominids. New research into extracting other longer surviving proteins, such as osteocalcin, has the potential to provide material for isotopic studies for much older material. An interesting development comes from the combination of microstructural studies and isotopic analyses to assess fine timescale changes in the diet or the environments of fossil individuals (Humphrey et al. 2004). The extension of isotopic analyses to new elements may also lead to interesting developments in this field. For example, sulfur isotopes in collagen along with strontium and oxygen in minerals can tell us...
about migration and movement patterns. Isotopic studies (especially of oxygen) will also likely contribute to a much greater knowledge of the environmental conditions and their rapid variation in the continental environment, a topic that so far remains much less explored than in oceanic environments and the ice caps.

28.4 Understanding evolutionary processes

The reconstruction of the evolutionary history of hominoids, and more specifically of fossil humans, has for a long time focused primarily on taxonomic and phylogenetic questions. Important methodological progress has been made in this field during recent decades. In particular, the use of cladistic approaches has provided a better theoretical background. Although these approaches also have their own limitations (Trinkaus 1990), they became indispensable for assessing the significance and the polarity of features. However, it should be underlined that the development of mathematical techniques to analyze size and shape, including 3D morphometrics, has led to the regression of some studies to a precladistic stage. The emphasis placed on the shape distances should not lead us to forget that morphological similarity is not a reliable way to analyze phylogenetic relationships when the polarity of the features is not taken into account.

A major problem, discussed extensively in recent years, centers around the features used by paleoanthropologists for cladistic analyses. These discussions have focused on features’ significance and on their relationships either to genetic determinism, or to environmental conditions and behavior, or to an interaction between the two. Beyond these discussions lie issues such as the independence of such features in their development and their homology when one passes from one species to another (Lieberman 1999; Wood 1999). These are critical questions for the analysis of the fossil evidence and the reconstruction of phylogenetic relationships from a parsimonious perspective. However, one may be reasonably optimistic in this matter, as experimental data and a better understanding of the precise genetic and epigenetic mechanisms underlying the development of features will resolve these questions. These may also bring answers to related problems such as the discrepancy sometimes underlined between biomolecular evidence and phylogenetic reconstructions based on the analysis of morphological features of the phenotype (Collard and Wood 2000; Strait and Grine 2004). They may also bring new light to the debate surrounding modular versus integrative models in the biological development of extinct organisms (Wagner 1996; Wagner and Altenberg 1996; Williams and Nagy 2001; Winther 2001).
As far as the recent stages of human evolution are concerned, it is reasonable
to expect that taxonomic and phylogenetic issues may become of minor interest
in the future, as the main taxa are identified and their phylogenetic relationships
understood. However, better understanding of the variability not only in extinct
taxa but also in living forms remains a crucial issue. Although some have
predicted the decline of such anatomical studies, it is still striking to contemplate
our lack of knowledge of the variability in living humans with respect to many
features commonly used in paleoanthropological research. After several centuries
of anatomical studies, we still desperately need valid longitudinal data on the
growth and development of many anatomical features. This lack of data is even
more dramatic when one considers the populations of living apes, our closest
relatives in the animal world; most of them will likely become extinct in the wild
before they have been properly studied.

Research may focus more on paleobiological issues. Changes in growth and
development processes during life history, in terms of timing and pattern, are
increasingly seen as powerful mechanisms to explain evolutionary changes.
Studies of extinct species consider this dimension with increasing frequency,
and developmental trajectories will hopefully be identified for different taxa as
will the effects of epigenetic phenomena. This is, of course, dependent on an
increase in the available paleontological material and also on a greater interaction
between paleoanthropology and developmental genetics. 3D morphometrics and
other mathematical tools have been identified recently as powerful tools for the
reconstruction of those developmental trajectories that can sometimes be mod-
eled (Ponce de León and Zollikofer 2001). Establishing reliable tools to assess
the calendar ages of immature individuals in the fossil record is of crucial
importance in this matter (Coqueugniot et al. 2004), and developing studies of
skeletal microstructure seem an inevitable way to address this problem.

Other aspects of the biology of extinct species might also become accessible
through progress in the extraction of biomolecules such as proteins. Osteocalcin
has recently been extracted from Neandertal remains and sequenced (Nielsen-
Marsh et al. 2005). In the future, extraction of proteins or lipids from ancient
material may even shed new light on the physiology of our ancestors and cousin
species. It should also be noted that the extraction of ancient proteins and their
sequencing may be extended much further back in time as some of these
molecules seem to resist taphonomic degradation much better than DNA.

In recent years, paleodemographic questions have become more and more
interesting to paleoanthropologists. Topics such as life history and longevity
are critically important to understanding the biological and social adaptations
of ancient groups, as well as to addressing questions of learning time during
individual life and the transmission of knowledge from one individual to another. Other paleodemographic parameters that appear to be important are the questions of population densities in given areas in a geological timeframe, and their possible catastrophic variation in relation to environmental changes. Although paleodemographic parameters have long appeared unreachable (Bocquet-Appel and Masset 1982, 1996), different methods of evaluating size fluctuation in ancient populations have emerged from genetic or paleogenetic studies. Although paleogenetic studies on the Neandertals did not revolutionize our views of their phylogenetic relationships, they did bring a new way to assess genetic variability in ancient populations, and consequently, size changes (Currat and Excoffier 2004; Serre et al. 2004). The animal models appear to be a tempting alternative for testing demographic fluctuations and their effects on genetic variability during the recent periods of the Pleistocene (Orlando et al. 2002). Such knowledge will allow a better understanding of the possible effects of demographic crashes and genetic bottlenecking on evolutionary processes themselves as well as the relative roles of genetic drift and natural selection. Combining isotopic analysis and microstructural studies will also allow the garnering of information such as the weaning age of fossil individuals. A fine knowledge of climatic environmental changes, sometimes perceptible on the scale of one human life, also brings new light to the way human populations have adapted biologically and culturally. In this perspective, a better integration of biological and cultural evidence seems necessary for a more thorough understanding of human evolution.

### 28.5 Chronology

The determination of the geological age of the fossil hominids is central to paleoanthropological work. Until recently, such determination has centered on the application of radiometric methods to the archeological context of the discoveries. Although available methods require improvement in their precision and in their calibration, their direct application to hominid specimens also represents major progress, especially for specimens anciently discovered and/or for which the context is unknown or inaccessible. Once more, the development of such approaches has been limited initially by the destructive aspects of these investigations. However, the emergence of new techniques, such as laser ablation, makes the analysis of light or heavy isotopes on precious specimens almost completely nondestructive. In the future, these studies may be applied routinely and become the best way to establish a precise chronology.

As far as the radiometric methods based on C\textsuperscript{14} disintegration are concerned, the development of mass spectrometry has allowed the direct dating of fossil
specimens by requiring only small amounts of matter for analysis. In the coming years, one may expect the establishment of a better calibration curve between 30,000–40,000 BP that will make the method more reliable in this time range of crucial importance to the history of modern human dispersal (Bard et al. 2004). In addition to calibration, contamination remains a major problem and the origin of the sampled carbon must be securely established; methods such as the ultrapurification of the collagen may allow for the control of this factor. Another future development will be to work with organic carbon from biomolecules that can be identified by sequencing as genuine fossil molecules belonging to the extinct organisms from which they were extracted. In practice, all this means that many C<sup>14</sup> dates acquired during the last decades may become meaningless because of the limitations of the techniques used to establish them. Large databases that have been built to process these dates by thousands and that provide a picture of biological and cultural evolution of humans, especially, at the time of the replacement of Neandertals by modern humans in Europe can be improved by a critical assessment of the compiled dates. However, the screening process has provided very contrasting pictures and has not satisfactorily solved all questions. This probably results from some bias in the selection process of the data retained, partly depending on the views that different authors have on the evolutionary and peopling processes involved. Eventually, such databases may become obsolete and will need to be rebuilt with more reliable geochronological information.

### 28.6 Picture of an ancestor

Every human society has built up physicotheological explanations to deal with the question of its origins. In the historical record, such explanations have been furnished by religions and mythologies, but from the middle of the nineteenth century, western societies substituted a scientifically based explication model for biblically based explanations. The question of human origins became the concern of the scientists rather than priests. However in 1863, T. Huxley, a main supporter of Darwin’s views, wrote: “The question of questions for mankind, the problem which underlies all others, and is more deeply interesting than any other, is the ascertainment of the place which man occupies in nature, and of his relationship to the universe of things. Whence our race has come; what are the limits of our power over nature; to what goal are we tending are the problems which present themselves anew, and with undiminished interest, to every man born into the world.” Almost 150 years later, this issue is still not free of ideological, if not metaphysical, constraints. This may partly explain why the public has developed
such an interest in this field of science. Aside from the inherent attraction of pictures of extinct worlds, any piece of evidence in paleoanthropological studies also becomes a matter of opinion and feeling, even for nonknowledgeable audiences. Prehistory is also consistently the topic of novels, films, and documentaries in which science always has to defend itself against fantasy. Museums and educational centers have become incredibly successful with this subject, showing increasing sophistication in their ways of responding to the demands of the public for pictures or 3D reconstructions. Although some of these reconstructions are today produced (Figure 28.1) using advanced techniques, they have their own limitations. It is certainly possible to provide reasonable reconstructions of the general anatomy of well-known fossil species. However, to date many fine anatomical details, such as skin, hair, and eyes, are beyond the range of

Figure 28.1
A reconstruction of a pre-Neandertal at the Landesmuseum für Vorgeschichte (Halle, Germany). Accurate methods have been developed to reconstruct soft tissues in fossil hominids. However today, like in the past, the picture of ancient humans primarily remains a projection of our own fantasies
scientific assessment. Unfortunately, they are also of crucial importance to the
way kinds of humans other than our own species appear to us. “Scientifically
based” reconstructions of fossil hominids filling the museums in Europe and
America may say much more about our way of perceiving human diversity than
about the actual aspect of these hominins. In this respect, the progress of our
reconstructions since the beginning of the twentieth century may be more limited
than is often assumed. Underlying notions of humans as belonging to different
species, and possibly contemporary in the past, are difficult to integrate not only
for the public but also for scientists from sister disciplines. The humanist
framework within which the human and social sciences developed in our uni-
versities may explain the difficulty that cultural anthropologists and archeolo-
gists, attached to the notion of “uniqueness” of the human being, face in dealing
with notions such as ape cultures or the multispecific nature of hominins. More
generally, in the post–Second World War era, new conceptions understandably
developed around human diversity that provided an ideological framework to
which paleoanthropological evolutionary models had to adapt. The questions of
Neandertal nature and abilities and their relationship to extant humans, in other
words the last well-documented divergence in our phylogenetic tree, is one arena
in which science and ideological preconceptions have clashed in a complex way.

In this interaction between scientists and the public, the media play an
important role. There are many reasons why scientists need to communicate
with the public. One is that the interest of the public partly justifies society’s
investment in this field of pure research. Another may result from more personal
reasons. For a department, for a team, for an individual, the visibility of obtained
scientific results becomes increasingly important as it impacts on possible per-
sonal promotion and political decisions to support this field of research in general
or a project in particular. Thus, the scientist and the reporter face each other in a
dialogue where each needs the other. The reporter needs material for exciting
articles; the scientist needs a reporter for publicity. In the past few decades, this
interaction has become increasingly important and has sometimes led to unde-
sirable effects. One obvious pitfall is that the public and reporters are more
interested in some issues than in others. Those problems most debated in the
media may be of limited interest to the scientific community and vice versa. Sex
between Neandertals and modern humans is an example of a question universally
addressed to the paleoanthropologists, and one danger is that, in the need to be
well represented in the media, scientists might be led to responding to questions
or even developing research interests geared to public attention. It is amazing to
see how well-developed press services have become not just in institutions
dedicated to public education and communication but also within research
structures as well.
Recently these interactions between scientists and the media have entered a new dimension, as personal issues or rivalries between individuals have become of themselves a matter of interest for the press. High-profile international scientific journals have developed “people sections” that deal almost exclusively with these subjects. Reporters have therefore become part of the scientific debate and actors in rivalries, by promoting opinions and sometimes by fueling controversies and conflicts in a way designed to make their articles more exciting.

28.7 Unbalanced ecology of paleoanthropology

Paleoanthropology is based on the study of specimens to which access, as we have seen, may be difficult. It is also based on sites and fieldwork. The result is that it can be a highly territorial activity, to an extent unequaled in other fields of science. Indeed, aside from scientific problems, the paleoanthropologist must also face a series of political and ethical issues. Although specimens discovered and published a long time ago should be fully accessible to the scientific community, this is not always the case. The situation is even more complex regarding specimens soon after their discovery and/or after a partial description. So far, the scientific community has not established a consensus on resolving such questions. The discoverer of a new specimen has a scientific and moral right to it and is granted priority in providing a scientific analysis of this material, alone or in collaboration with other specialists. However, this well-accepted notion is often blurred by complications. One such complication can result from the multiplicity of the discoverers involved and from lack of agreement at the time of the discovery or later. And many discoveries occur during the course of archeological excavations conducted by teams that were not anticipating the possibility of hominin discoveries. Another problem can result from an abusive extension of the time spent between a discovery and the publication of a reasonably comprehensive description of it. The competition that is natural in science is sometimes displayed in a negative form, such as preventing challengers from accessing material, which may be used as a more efficient way to surpass them than producing better scientific results.

Similar situations have developed with respect to site and field access. Most commonly, research teams obtain the monopoly of the study of one site or a geographical area for a certain length of time in order to conduct a defined scientific program. However, apart from this formal arrangement, there are a number of situations where informally and based on political influence, tradition, or nationalistic issues, institutions manage to secure a geographical domain of influence. This is often the case when excavations or field operations are conducted by scientists from western countries in less developed areas. Often,
this is facilitated by the fact that the studied areas are located in countries lacking indigenous research in the field of paleoanthropology and/or scientists trained in this discipline. In such cases, the work is conducted under the authorization of local administrations that are primarily preoccupied by the conservation of their national patrimony. Here again, different institutions or scientific communities may develop some level of competition in guaranteeing their access to the field. Different countries have developed different regulations restricting the exploitation of archeological and paleontological material. Situations in which fossil specimens can simply be transferred from the country of their discovery to scientific institutions or museums in Europe or America have almost completely disappeared today.

Many scientists have felt compelled to develop balanced collaboration with the host countries in which they conduct their research, in particular, by helping with the conservation of the material and with the training of local scientists. Furthermore, many countries outside of the western world have managed to develop their own programs and scholars, and the trend is more and more to develop joint projects, although a very unequal equilibrium in terms of financial contribution and/or scientific expertise can lead to bitter conflicts. One thing is clear: the time of scientific colonialism is over (or will be over soon), and although in an ideal world, fossils and sites should be accessible to “everyone,” we are still far from this situation. Archeological and paleontological materials are considered as part of the national patrimony in most countries, yet the future of the field lies in fair and fruitful international collaborations.

1 Primate Origins and Supraordinal Relationships: Morphological Evidence

Mary T. Silcox · Eric J. Sargis · Jonathan I. Bloch · Doug M. Boyer

Abstract

There are five major scenarios that have been advanced to account for the early events in the origination of the order Primates: a transition from terrestriality to arboreality, the adoption of a grasp‐leaping mode of locomotion, the evolution of features for visual predation, an adaptation to terminal branch feeding occurring during angiosperm diversification, or a combination involving terminal branch feeding followed by visual predation. These hypotheses are assessed using both neontological and fossil data. Of the five scenarios, the angiosperm diversification hypothesis is not contradicted by modern data and is found to be the most consistent with the fossil record. In particular, the evolution of features for manual grasping and dental processing of fruit in the earliest primates (primitive plesiadapiforms), and the subsequent development of features for better grasping and more intense frugivory in the common ancestor of Euprimates and Plesiadapoidea, is consistent with a close relationship between early primate and angiosperm evolution. All the other scenarios are less consistent with the pattern of trait acquisition through time observed in the fossil record. Consideration of non‐euprimates (e.g., scandentians and plesiadapiforms) is found to be essential to viewing primate origins as an evolutionary process rather than as an event.

1.1 Introduction: what is a primate?

Perhaps the most fundamental issue facing students of primate origins can be summarized by a simple question: what is a primate? A clear concept of the diagnosis and taxonomic composition of Primates is essential to providing a coherent understanding of when and why the order separated from the rest of Mammalia. Attempts to define the order Primates have typically started by considering which features of modern primates are present in multiple primate species and are distinctive relative to other mammals. Four major adaptive
complexes of traits have been recognized as characteristic of primates of modern aspect (=Euprimates Hoffstetter 1977; see Mivart 1873; Le Gros Clark 1959; Napier and Napier 1967; Martin 1968, 1986, 1990; Szalay 1968; Cartmill 1972, 1992; Szalay et al. 1987):

(1) Traits associated with grasping. These include relatively longer hand and foot phalanges, a divergent thumb and big toe, and digits tipped with nails rather than claws.

(2) Traits associated with leaping. Although such features have been lost in some extant primates (e.g., *Homo sapiens*), the most primitive euprimates have leaping characteristics that include hindlimbs that are long relative to the forelimbs and modified ankle bones.

(3) Traits associated with improvements to the visual system. These features include large eyes, convergent orbits, and a postorbital bar or septum. The larger and more complex brain of modern primates compared to other euarchontans (see below) may also be associated, in part, with this complex. A smaller apparatus for the sense of smell is presumably associated with an increasing reliance on vision as well, leading to a short snout and proportionally reduced related areas of the brain.

(4) Dental traits associated with herbivory. Relative to specialized insectivores, primates possess teeth that are low crowned, with blunt and bulbous (bunodont) cusps and broad talonid basins, which are features related to eating non-leafy plant materials (e.g., fruit) rather than insects or meat.

Presence of a petrosal bulla has also often been cited as an ordinally diagnostic primate trait (e.g., Cartmill 1972) but its adaptive significance (if any) is unclear.

Defining the order Primates using observations on living taxa as a starting point is problematic because these traits are unlikely to have evolved simultaneously. Instead, a definition that recognizes the process of primate evolution and that encompasses the earliest, possibly stem, members of the order will have greater explanatory power. We will return to this problem below.

### 1.2 Ecological scenarios for primate and euprimate origins

Researchers investigating primate origins have typically focused on building an ecological scenario that could explain the evolution of one or more of these adaptive complexes. The earliest such scenario is the arboreal hypothesis of
primate origins, which traces its roots back to the work of G. Elliot Smith and F. Wood Jones in the early part of the twentieth century. The arboreal hypothesis was extended and broadly popularized by W.E. Le Gros Clark (1959). In this hypothesis, grasping extremities were seen as having value for more secure climbing, and the distinctive primate orbital features were explained as being useful for judging distances in the trees during leaping.

All of the other ecological scenarios that have been developed assume a life in the trees for ancestral primates but seek to go beyond simple arboreality to consider more specific types of behavior. Szalay and colleagues (Szalay and Delson 1979; Szalay and Dagosto 1980, 1988; Szalay et al. 1987; Dagosto 1988) considered a derived locomotor mode, grasp-leaping, to have driven the evolution of most of the features that characterize euprimates, including those of the visual apparatus. They linked the ability to rapidly jump from branch to branch with the need to be “... subsequently securely anchored” (Szalay and Delson 1979 p 561) to the landing point. Visual changes were relevant to judging distances in rapid, leaping locomotion (Szalay and Dagosto 1980). In this hypothesis, anatomical changes for grasp-leaping were preceded by a shift to a more herbivorous diet in the primitive primates (i.e., plesiadapiforms) ancestral to Euprimates (Szalay 1968, 1972; Szalay and Dagosto 1980; Szalay et al. 1987).

Cartmill (1972, 1974, 1992) focused on visual predation as key to the origin of Euprimates. The visual predation hypothesis linked visual features beneficial to accurately gauging the distance to prey items with grasping, clawless hands and feet that could provide both a secure hold on narrow supports, and a prehensile apparatus for snatching prey. Because he thought they lacked orbital specializations and grasping features, Cartmill advocated excluding plesiadapiforms from Primates.

Sussman (1991; Sussman and Raven 1978) suggested a link between the origin of Primates and the Cenozoic diversification of angiosperms (i.e., trees that produce fruit and flowers). He agreed with Szalay that a key event in early primate evolution was the invasion of the “arboreal mixed feeding adaptive zones” (Sussman and Raven 1978 p 734) in the Paleocene. This involved increased use of non-leafy plant resources by early primates as angiosperms developed features that made them more tempting to non-insect seed and pollen dispersers, such as specialized flowers and larger fruit. With the appearance of still larger propagative plant organs (e.g., fruit, seeds) near the Paleocene–Eocene boundary, the ancestral Euprimates developed features for entering terminal branches to better exploit these resources.

There are two major classes of data that have been used to assess the relative validity of these various ecological scenarios. The first “tests” various ecological functions assigned to character complexes in the different models using the
comparative method. The second employs the fossil record to document the sequence of anatomical changes that occurred in primate evolution and seeks to tie these changes to adaptive shifts.

### 1.2.1 Comparative method

Cartmill (1970, 1972, 1974) assessed the then prevalent arboreal hypothesis from the point of view of the diversity of modern arboreal animals. He argued that if living in an arboreal habitat could explain the distinctive features of primates, then these traits should also be found in other arboreal forms, and particularly in the arboreal members of groups that also include terrestrial species. Cartmill found that arboreal animals in general do not have features similar to those seen in modern primates. For example, arboreal squirrels are not more primate-like than terrestrial squirrels in grasping traits, such as a reduction of the claws, or in vision-related features like the degree of orbital convergence. Nonetheless, arboreal squirrels are successful at many of the same behaviors practiced by primates, including making reasonably long jumps and foraging among slender branches. He argued that forward facing orbits, while enhancing stereoscopy, decrease parallax and with it the ability to judge distance at longer ranges. For this reason, orbital convergence is not a very useful trait for gauging distances in a jump but is very effective for visualizing objects close to the face. On the basis of these comparisons, it seems unlikely that the distinctive adaptive complex of euprimates can be simply linked to a shift to an arboreal mode of life.

Cartmill’s own hypothesis of primate origins, visual predation, has also been attacked from the standpoint of modern analogy. Garber’s (1980) (but see Crompton 1995) work on the tamarin *Saguinus oedipus* revealed a feeding mode similar to that discussed by Cartmill in an animal that possesses claw-like nails. The evolution of claw-like nails in callitrichines, who nonetheless practice visual predation, undermines the association between this feeding behavior and specialized grasping. Sussman (1991) (see also Crompton 1995) pointed out that most living primates are omnivores, not specialized insectivores, and that their methods of prey capture often emphasize scent and hearing over vision—tarsiers have actually been observed to capture their prey with their eyes closed (Niemitz 1979)! Furthermore, many of the insects eaten by extant primates are crawling forms captured on the ground, not flying forms plucked from the air. If living primates are not typically specialized visual predators, it is not clear why we would expect morphologically similar extinct species to be.
Alternatively, some authors (Sussman and Raven 1978; Sussman 1991; Crompton 1995) have sought analogues for early primates among frugivores, such as old world fruit bats. However, Ravosa and Savakova (2004) recently found no relationship between the degree of orbital convergence and the level of frugivory in a broad array of modern taxa. Nonetheless, the absence of primate-like visual features in some modern visual predators (e.g., mongooses and tupaiid treeshrews; Cartmill 1992) suggests that there is no simple relationship between forward facing orbits and this mechanism for prey capture in mammals. A possible “solution” to this criticism, that the euprimate-like mechanism of orbital convergence for prey capture is only needed in nocturnal animals (Allman 1977; Cartmill 1992), would be refuted if the earliest euprimates were not nocturnal (see below).

Sussman’s (1991; Sussman and Raven 1978) angiosperm diversification hypothesis has been criticized based on the lack of an association between the diversification of angiosperms and the evolution of adaptations in arboreal marsupials that converge on those seen in primates (Cartmill 1992). Nonetheless, in a study of the somewhat primate-like South American didelphid marsupial *Caluromys derbianus*, Rasmussen (1990) did find some support for Sussman’s model, in that a substantial part of its diet comes from terminal branch fruit feeding in a manner similar to modern primates. This study additionally provided some support for Cartmill’s model, in that *Caluromys* is also a visual predator that occasionally grasps prey with its hands. However, *Caluromys* does not have particularly convergent orbits (Rasmussen 1990), weakening substantially the link between this anatomical feature and visual predation. Rasmussen’s study can be seen as providing a fifth composite scenario for primate origins that has ancestral primates initially venturing out onto terminal branches to find fruit and other plant parts, with the secondary evolution of features for prey capture to capitalize on the insect resources they found in this milieu (Rasmussen 1990; Cartmill 1992).

The grasp-leaping scenario of primate origins (Szalay and Delson 1979; Szalay and Dagosto 1980, 1988; Szalay et al. 1987; Dagosto 1988) is less susceptible to criticisms based on modern analogy than the other ecological scenarios because it does not depend on a general ecological relationship for its validity. Rather, it stems from a “fossil-first” approach to considering adaptive change, beginning with the evolutionary transitions documented in the fossil record, and then attempting to determine their adaptive meaning in a form-functional context. This highlights a major contrast in approaches to the question of primate origins between the major combatants in the debate. Under Szalay’s approach, the unique origins, constraints, and evolutionary histories of different mammalian
lineages mean that adaptive explanations applied to one group need not apply to any other. Cartmill, however, argues that “[t]he only evolutionary changes we can hope to explain are . . . parallelisms: recurrent modifications that show up over and over again in different lineages for the same structural or adaptive reasons . . .” (Cartmill 1993 p 226).

One problem with Cartmill’s approach is that it assumes that all adaptive shifts of interest must be parallelisms because otherwise there would be no possibility of explaining them. This reflects a more general problem with the use of modern analogy to “test” hypotheses about evolution. Any historical event is by definition a unique occurrence, even if it is more or less similar to other such unique occurrences that have taken place in other lineages. There is no reason to believe that everything that has happened once has necessarily happened twice. The evolutionary process that produced primates began at a unique starting point (i.e., the divergence of this clade from the rest of Mammalia) and finished at a unique endpoint (i.e., the diversity of extant species). The starting point was heavily constrained by the evolutionary history of what went before, and the adaptive significance of the features evident at the current endpoint is dependent not only on the current usage of a given trait, but also on the biological needs of all the animals that existed along the evolutionary lineage leading to a particular modern species. Modern non-primates that appear similar to primates might have passed through series of adaptive stages quite different from those experienced by our distant ancestors and thus may have arrived at their current form by a very different path. For this reason, arguments that ancient marsupials did not acquire their primate-like traits as a result of angiosperm diversification are not directly relevant to the question of whether or not primates did. The study of modern primates, or modern non-primate analogues, in isolation cannot provide a demonstrably accurate picture of the process of primate origins—it can only yield hypotheses that are more or less plausible for subsequent testing by the fossil record.

A somewhat analogous situation occurred in the early history of human paleontology. In the early part of the twentieth century, quite plausible scenarios were proposed that suggested either a large brain or bipedal locomotion as being the first-occurring distinct human trait (Lewin 1987). With the discovery of the australopiths—primitive human ancestors with adaptations for bipedal locomotion but relatively small brains (McHenry and Coffing 2000)—any “brains first” scenario was decisively falsified, no matter how plausible it may have seemed on the surface. And so too must any ecological scenario of primate origins be considered falsified if the predicted pattern of trait acquisition is not matched by the fossil record.
1.2.2 Fossil record

1.2.2.1 Primate supraordinal relationships

The origin of Primates was a process, not a single event. The distinctive primate traits listed in the introduction likely did not arise in an evolutionary instant. If this is true, the elucidation of the adaptive process of primate origins relies centrally on knowing the relationships of taxa at the base of the primate tree to understand the evolutionary steps taken to build the first euprimate.

In recent years, the supraordinal relationships of primates among living mammals have been sought in Archonta, a group named by Gregory (1910) to include primates, dermopterans (flying lemurs or colugos), treeshrews, chiropterans (bats), and elephant shrews. Modern conceptions of Archonta (McKenna 1975; Szalay 1977; Novacek and Wyss 1986; Novacek 1992; McKenna and Bell 1997) exclude elephant shrews but postulate a close evolutionary relationship between the first four groups based on morphological similarities (Silcox et al. 2005). Within Archonta, primates have traditionally been allied with treeshrews, a group that was for many years included in the order Primates (Carlsson 1922; Le Gros Clark 1925, 1926, 1959), but which are now classified in their own order, Scandentia (Butler 1972; McKenna and Bell 1997). Novacek (1992) provided a consensus morphological solution for archontan relationships, with links between Scandentia and Primates on the one hand and Dermoptera and Chiroptera (=Volitantia) on the other.

More recent molecular and morphological studies have questioned this view. Molecular studies have consistently failed to find a close relationship between bats and the other archontans—rather, chiropterans have generally grouped with carnivores and ungulates (Pumo et al. 1998; Miyamoto et al. 2000; Liu et al. 2001; Murphy et al. 2001a, b; Springer et al. 2003, 2004). The other three orders have clustered together in many recent molecular studies (Adkins and Honeycutt 1991; Waddell et al. 1999; Liu et al. 2001; Murphy et al. 2001a, b; Springer et al. 2003, 2004), leading Waddell et al. (1999) to propose the name Euarchonta for a group including Primates, Dermoptera, and Scandentia. Within Euarchonta, consistent molecular support for the traditional grouping of primates and treeshrews has also been lacking, with a Scandentia-Dermoptera (=Sundatheria; Olson et al. 2005) link being supported by several recent analyses (Liu et al. 2001; Murphy et al. 2001a, b; Springer et al. 2003, 2004). If this hypothesis is correct, it implies that the best model for the ancestor of primates based on extant forms is represented by the reconstructed common ancestor of Euarchonta, not by treeshrews in isolation. In particular tupaiids, the diurnal family of treeshrews most often used for comparison to primates (Beard 1993a), become less relevant as
ancestral primate models. The sole living member of the family Ptilocercidae, *Ptilocercus lowii*, is the extant treeshrew closest to the base of Scandentia (Olson et al. 2004, 2005) and shares many more features than tupaiids with dermopterans (Sargis 2001a, 2002a, b, c, d, 2004, in press). These shared features are present in *Ptilocercus* and dermopterans in spite of some fundamental differences between their locomotor modes (gliding in dermopterans, arboreal quadrupedalism in *Ptilocercus*; Sargis 2001a, 2002a, b, c, d, 2004, in press), implying that they may be ancestral for the common ancestor of Sundatheria, or even of Euarchonta. As such, *P. lowii* might provide us with the best living model for the common ancestor of Primates (Figure 1.1).

Discovery of new fossil specimens has also led to significant challenges to the view of archontan relationships portrayed by Novacek (1992). In 1990, two papers (Beard 1990; Kay et al. 1990) documented specimens of taxa classified in the plesiadapiform family Paromomyidae that were interpreted as providing strong support for a plesiadapiform–dermopteran relationship. Beard (1989,
1990, 1993a, b) even went so far as to postulate that paromomyids and another plesiadapiform family, Micromomyidae, practiced a dermopteran‐like, mitten‐gliding mode of locomotion.

The relevance of these views to primate origins is related to the systematic position of plesiadapiforms. “Plesiadapiformes” is a paraphyletic grouping of extinct fossil mammals known from the Paleocene and Eocene of North America, Europe, Asia, and possibly Africa (Russell 1964; Beard and Wang 1995; Fu et al. 2002; Smith et al. 2004; Tabuce et al. 2004; Silcox and Gunnell in press). Represented by more than 120 species classified into 11 or 12 families (depending on whether or not the enigmatic African azibiids are included: Silcox 2001; Tabuce et al. 2004), plesiadapiforms represent a very diverse radiation and form a significant component of the faunal record from many Paleocene localities (Rose 1981; Gunnell et al. 1995). The systematic position of plesiadapiforms has been a long‐standing matter of debate. Most early workers classified plesiadapiforms in Primates, often specifically in Tarsiidae (Matthew and Granger 1921; Gidley 1923), based largely on dental similarities. More recent workers have often viewed plesiadapiforms as the first radiation of the order Primates, more primitive than any modern group (Szalay and Delson 1979; MacPhee et al. 1983; Szalay et al. 1987). This hypothesized plesiadapiform–euprimate relationship is not without its detractors. Martin (1968) and Cartmill (1972) were the first to seriously question the primate status of plesiadapiforms. In both of these cases, each worker’s emphasis was on forming a clearer definition of the order Primates, rather than providing an outline of primate supraordinal relationships, leaving plesiadapiforms either in limbo or classified as part of a wastebasket “Insectivora.” Such an approach ignores the possibility that identifying ancestral fossil forms would be essential to understanding the adaptive steps leading to the common ancestor of Euprimates.

Wible and Covert (1987) also suggested removing plesiadapiforms from the order Primates on the grounds that cranial evidence was more supportive of a scandentian–euprimate tie than a plesiadapiform–euprimate one. They argued that the dental evidence linking plesiadapiforms to euprimates consisted only of ill‐defined “trends” (Wible and Covert 1987 p 9). This conclusion was not based on any detailed consideration of teeth, however, which is particularly problematic since the euprimate–plesiadapiform relationship had always been supported largely by dental evidence. Furthermore, one of the critical basicranial features that they cited in support of a Scandentia–Euprimates clade excluding plesiadapiforms has since been found in a paromomyid plesiadapiform (a bony tube for the internal carotid nerves and/or artery; Silcox 2003).

Beard’s (1989, 1990, 1993a, b) and Kay et al.’s (1990, 1992) suggestion of a plesiadapiform–dermopteran relationship offered a novel reason for excluding
plesiadapiforms from Primates. Although their papers agreed on the plesiadapiform–dermopteran tie, the analyses performed by these authors produced hypotheses of relationships for the rest of Archonta, including the placement of Euprimates, which were otherwise almost entirely contradictory (\textodot\ Figure 1.2).

Figure 1.2
(a) Kay et al.’s (1992: fig. 11) maximum parsimony cladogram, redrawn with “Euprimates” substituted for their “Primates” following the terminology in use here; (b) relationships of taxa included by Kay et al. taken from Beard’s (1993a: fig. 10.1) analysis. Beard did not explicitly include any lipotyphlan insectivores, implying that he considered them to lie outside of the ingroup. The only areas of congruence between these hypotheses are the monophyly of Chiroptera and the relationship between the paromomyid Ignacius and the dermopteran Cynocephalus. Otherwise they are entirely in conflict.

Kay et al. (1992) failed to support Archonta or Euarchonta, with plesiadapiforms and dermopterans falling outside of lipotyphlan insectivores on their cladogram, and presumably far distant from bats, primates, and tree shrews (\textodot\ Figure 1.2a). Likely because of their common focus on cranial data, Kay et al. (1992) agreed with Wible and Covert (1987) that Scandentia is the sister taxon to Euprimates. Beard (1993a; \textodot\ Figure 1.2b), on the other hand, found a close relationship between modern dermopterans and plesiadapiforms (his “Dermoptera”; Beard 1993a, b) and euprimates, a group he named Primatomorpha. The sister group to this clade in Beard’s (1993a) analysis was Chiroptera, with Scandentia falling out as the basal-most group of archontans. These two analyses suggested very different taxa as being central to issues of primate origins—plesiadapiforms and dermopterans on the part of Beard and tree shrews on the part of Kay and colleagues.
Beard’s (1989, 1990, 1993a, b) and Kay et al.’s (1990, 1992) conclusions have been challenged by numerous studies on both phylogenetic and functional grounds (Krause 1991; Szalay and Lucas 1993, 1996; Wible 1993; Wible and Martin 1993; Van Valen 1994; Runestad and Ruff 1995; Stafford and Thorton 1998; Hamrick et al. 1999; Stafford and Szalay 2000; Boyer et al. 2001; Bloch and Silcox 2001, 2006; Silcox 2001, 2003; Bloch and Boyer 2002, 2003; Sargis 2002d, in press; Silcox et al. 2005). Some of the shortcomings identified by these authors include a lack of appropriate sampling of Scandentia (Sargis 2002d, in press), problems with the identifications of specimens (Krause 1991; Hamrick et al. 1999; Boyer et al. 2001), features that were missed or misinterpreted (Simmons 1994; Stafford and Thorton 1998; Bloch and Silcox 2001; Silcox 2001, 2003; Sargis 2002d), and a lack of appropriate character sampling in their almost entire exclusion of dental data and omission of hypothesized volitant synapomorphies (Silcox 2001; Sargis 2002d, in press; Silcox et al. 2005). Since the publication of Kay et al. (1992) and Beard (1993a, b), numerous new specimens of plesiadapiforms have been uncovered, documenting previously poorly known or totally unknown anatomical regions (Boyer et al. 2001; Bloch and Silcox 2001, 2003, 2006; Bloch and Boyer 2002, 2003; Figure 1.3). The impact of these specimens also needs to be considered in terms of their relevance to plesiadapiform and euprimate relationships and taxonomy.

Silcox (2001) sought to remedy some of the problems identified above with more extensive character and taxon sampling, including a large dental dataset, inclusion of hypothesized volitant synapomorphies, reconsideration of all characters, and codings for cranial and dental features of the scandentian *P. lowii*. She examined 181 dental, postcranial, and cranial characters for 85 species. Her results (Figure 1.4a) supported a plesiadapiform–euprimate relationship to the exclusion of dermopterans. Dermoptera grouped with Chiroptera when bats were included and with Scandentia when Chiroptera was excluded from the analysis. The Dermoptera–Scandentia grouping is also found in many other recent molecular and morphological studies (Liu et al. 2001; Murphy et al. 2001a, b; Springer et al. 2003, 2004; Sargis 2002d, in press).

We have since expanded Silcox’s data matrix by including data from new plesiadapiform skeletons, new postcranial characters, and novel postcranial data from *P. lowii* (Bloch and Boyer 2003; see also Bloch et al. 2002, submitted; Figure 1.4b). This analysis supports a more basal position for micromomyids and a sister group relationship between Plesiadapoidea (including Plesiadapidae, Carpolestidae, Saxonellidae, and the basal form *Chronolestes simul* from Asia) and Euprimates. Thus, this analysis also supports the idea that plesiadapiforms were a paraphyletic stem group at the base of the order Primates. Plesiadapiforms,
Skeletons representing three plesiadapiform families were recovered from Late Paleocene limestones (Bloch and Boyer in press: fig. 3). Paromomyidae is represented by (a) *Acidomys hebeticus* (UM 108207) and (b) *Ignacius* cf. *I. graybullianus* (UM 108210). Carpolestidae is represented by (c) *Carpolestes simpsoni* (UM 101963; Bloch and Boyer 2002: fig. 2a). Plesiadapidae is represented by (d) *Plesiadapis cookei* (UM 87990). Scales = 5 cm
and specifically plesiadapoids, are crucial for establishing primitive states for Euprimates in this hypothesis.

One implication of these results is that plesiadapiforms might be best included in the order Primates (Silcox 2001, in press), in a return to earlier...
conceptions of how to define the group (Szalay 1975; Szalay and Delson 1979; Szalay et al. 1987). This notion has received some recent support from a previous proponent of the plesiadapiform–dermopteran clade (Kay 2003). The ecological scenarios discussed above take as their starting point the common features of modern primates. Plesiadapiforms do not possess all of these traits. With the recognition that plesiadapiforms constitute the primate stem lineage, discussing “primate origins” then involves dealing with at least two sets of evolutionary transitions—first, the branching off of the primate stem and evolution of the earliest primate (Purgatorius; Van Valen and Sloan 1965; Johnston and Fox 1984) and second, the origin of Euprimates. Earlier discussions of “primate origins” that explicitly endeavored to explain only the latter transition (Cartmill 1972; Rasmussen 1990; Sussman 1991) are inherently flawed in trying to account for the concerted evolution of character complexes that did not arise at the same time, mixing the effect of multiple evolutionary transitions. This is true even if one chooses to classify plesiadapiforms as a non-primate sister group to the order.

It is possible to formulate and test predictions about the sequence in which anatomical transformations occurred pursuant to the various ecological scenarios discussed above (Bloch et al., submitted) by the use of the hypothesis of primate supraordinal relationships given in Figure 1.4b. In the same way that “brains first” scenarios of human origins relied on the evolution of large brains before features for bipedalism, so the ecological scenarios of primate origins require a certain order for the addition of traits through time for them to be considered valid.

1.2.2.2 Predictions for ecological scenarios of primate and euprimate origins

Under the arboreal hypothesis, the prediction is inherent in the model that the evolution of characteristically primate traits coincided with a move into an arboreal habitus. If, on the other hand, the ancestors of Primates were already arboreal while lacking such traits, then the arboreal hypothesis would be effectively falsified. It would also be falsified if the evolution of characteristic primate features pre-dated a move to the trees, for example if forward facing orbits were found in an animal otherwise adapted for a terrestrial habitus.

The grasp-leaping hypothesis posits a relationship between the evolution of features for grasping with those for leaping. As such, if grasp-leaping is to function as an explanatory hypothesis for euprimate origins, then the evolution of these features should coincide in time. Visual features for improved stereoscopy should also coincide with the adoption of a more rapid, leaping,
locomotor mode. Although it may still be true that early euprimates were functionally grasp-leapers, if such a coincident evolution of the relevant traits is not found then this hypothesis would lose its explanatory power as a central motivating force in euprimate origins.

Cartmill (1992), in discussing the development of his visual predation hypothesis, wrote,

- Noting that marked optic convergence is also a characteristic of cats and many other predators that rely on vision in tracking and nabbing prey, Cartmill sought the adaptive significance of this trait in the predatory habits of small prosimian primates like Microcebus, Loris, and Tarsius, which track insect prey by sight and seize them in their hands. Grasping extremities and claw loss, he suggested, had also originated as predatory adaptations . . . (Cartmill 1992 p 107; emphasis ours)

This statement implies that these features should be tied together temporally, since they were acquired as part of the same adaptive shift to a more predatory pattern of behavior. Kirk, Cartmill, Kay, and Lemelin (2003 p 741b) claimed that Bloch and Boyer (2002) mischaracterized visual predation suggesting that “As originally formulated (Cartmill 1972), Cartmill’s thesis interprets the prehensile, clawless extremities of primates as adaptations for locomotion on slender arbo-real supports.” Regardless of these authors’ current opinions, this is directly contradicted by Cartmill’s own account (1992), quoted above, of what he meant when he formulated this hypothesis.

Since visual predation involves an increasing reliance on insect prey, this should also be reflected in the teeth of the earliest euprimates. This is true even if these forms were grasping prey with their hands rather than teeth (contra Cartmill 1972, 1974) because dental features for insectivory reflect not only prey capture but also processing of food items with the unique physical properties of insects. If, however, early primates or euprimates were found to be equally or less insectivorous than their forbears, or a disassociation were to be found between grasping and visual traits, then visual predation would be refuted as a central motivating force in early primate evolution. Since visual predation also relies to some degree on nocturnality (Allman 1977; Cartmill 1992), a finding that the earliest primates or euprimates were diurnal would substantially weaken this hypothesis.

The angiosperm diversification hypothesis predicts two stages in the evolution of primates. First, with the initial exploitation of the arboreal mixed feeding adaptive zone, a dental shift reflecting more use of plant resources should be seen. Second, as the terminal branches were invaded and the use of the food resources from this milieu was intensified, grasping and dental features reflecting these changes should appear. Disassociation between dental traits for eating fruit or
flowers, and those indicating the ability to access terminal branches, would weaken the explanatory power of this hypothesis.

Similarly, the combined hypothesis involving first terminal branch feeding on fruit, and then visual predation, suggested by Rasmussen (1990), requires that “the earliest euprimates had grasping feet and blunt teeth adapted for eating fruit, but retained small, divergent orbits like those of *Plesiadapis*” (Cartmill 1992 p 111). Subsequent evolution should add features for visual predation, such as forward facing orbits and teeth with improved capabilities for processing insects, to this basic model. If, however, convergent orbits evolved at the same time as grasping feet or blunt teeth, or their appearance was not coincident with the evolution of teeth better designed for eating insects, then this model would be effectively falsified.

### 1.2.2.3 Assessment of ecological scenarios

With the well-supported pattern of relationships found by the current authors (Figure 1.4b), it becomes possible to consider the predictions outlined above in light of what we know about the fossil record (Figure 1.5). In terms of the arboreal hypothesis, the inferred arboreal habits of all plesiadapiforms known from postcranials (Szalay and Decker 1974; Szalay et al. 1975; Szalay and Dagosto 1980; Szalay 1981; Szalay and Dradhorn 1980; Beard 1989; Gingerich and Gunnell 1992; Boyer et al. 2001; Bloch and Boyer 2002, 2003, in press) make it clear that the ancestors of Euprimates were already arboreal. This is further indicated by the inclusion of Primates in Archonta or Euarchonta because this supraordinal group likely had an arboreal ancestor (Szalay and Dradhorn 1980; Sargis 2001a, 2002e). As such, distinctively euprimate traits cannot be linked to a simple move from a terrestrial to an arboreal habitus. The fact that *P. lowii*, an arboreal mammal, may be the best living model for the ancestor of Archonta or Euarchonta and possibly for Primates (Sargis 2001a, 2002e; Bloch et al. 2003), strongly suggests that arboreality is a feature that evolved prior to the base of the primate radiation (Szalay and Dradhorn 1980). Many of the features that have been cited as possible archontan or euarchontan synapomorphies (Szalay and Dradhorn 1980; Szalay and Lucas 1996; Sargis 2002d; Silcox et al. 2005) can also be linked to arboreal locomotion. It is likely that arboreality evolved in the ancestor of Euarchonta (Szalay and Dradhorn 1980; Sargis 2001a, 2002e), and that this trait was retained (but did not originate) in the ancestor of Primates.

The evolution of grasping is central to the assessment of both the graspleaping and visual predation hypotheses. With a better fossil record for plesiadia-piforms, it is now clear that grasping is not a single character state or set of
coordinated transformations. The ancestral euarchontan was likely capable of *Ptilocercus*-like grasping (Szalay and Dagosto 1988; Sargis 2001b, 2002b, e, 2004). As Bloch and Boyer (2002, 2003) demonstrated, the evolution of fully euprimate-like grasping was at least a two-stage process. Features for manual grasping, including relatively long digits of the hand, are present in all plesiadapiforms known from relevant material, with the exception of plesiadapids who have secondarily lost this trait (Bloch and Boyer 2002, 2003; Boyer et al. 2004). Euprimate-like pedal grasping, including a divergent big toe with a nail, is present in *Carpolestes simpsoni*, and can be reconstructed as having evolved in the common ancestor of Plesiadapoidea and Euprimates (Bloch and Boyer 2003).

No plesiadapiforms known show any features associated with specialized leaping (Szalay et al. 1975; Szalay and Dagosto 1980; Beard 1989; Gingerich and Gunnell 1992; Bloch and Boyer 2002, in press). *Carpolestes simpsoni*, for example,
lacks the relatively long legs typically seen in a leaping mammal, indicating that it was a more generalized arboreal quadruped (Figure 1.3; Bloch and Boyer 2002). The first primate taxa with clear leaping characteristics are early euprimates such as Cantius and Omomyx (Rose and Walker 1985; Anemone and Covert 2000). Although current evidence suggests that leaping and visual traits did evolve at the same time, there is a distinct offset between the evolution of features related to grasping and those for leaping. In light of this, although early euprimates were likely grasp-leapers and leaping may have evolved in the ancestral euprimate (Szalay and Dagosto 1980, 1988; Dagosto 1988), the evolution of grasp-leaping was not the event that shaped the origin of primates or euprimates.

Similarly, no known plesiadapiforms show any of the specialized features of the orbital system that are associated with euprimate-like vision, including a complete postorbital bar, convergent orbits, reduced snout, or an enlarged and reorganized brain (Russell 1964; McKenna 1966; Szalay 1969, 1972; Kay and Cartmill 1977; Kay et al. 1992; Bloch and Silcox 2003, 2006). Therefore, there is an offset between the evolution of grasping and visual features. As such, their coordinated acquisition as part of a shift to a new mode of feeding, visual predation, was not the decisive event in shaping primate or euprimate origins.

It is still possible that adding visual predation to the behavioral repertoire of euprimates was an important event in the evolution of this group, in which grasping features effectively acted as an exaptation (=preadaptation). However, there is evidence that leads one to doubt this scenario, however. First, as discussed above, visual predation becomes mechanistically implausible if the earliest euprimates were diurnal (Allman 1977; Cartmill 1992). Ni et al. (2004) recently published a primitive euprimate skull from Asia that they interpreted as having been diurnal. Although there are some problems with this conclusion (Heesy and Ross 2004; Martin 2004; Bloch and Silcox 2006), it draws attention to the fact that the ancestral activity period for euprimates remains a matter of debate. Second, if euprimates did undergo a transition to becoming more focused on visual predation, then they should have teeth that are indicative of a more insectivorous diet than their precursors. This is not demonstrably true. The earliest known euprimate, Altiatlasius koulchii, has extremely low-crowned teeth with very bunodont cusps (Sige et al. 1990), which is not consistent with a predominantly insectivorous diet. Of the two best-documented groups of early euprimates, adapids are usually viewed as being frugivorous and omomyids as omnivorous or frugivorous (Rose 1995; Strait 2001). The only gut contents known for a primitive fossil primate (from the adapid Godinotia from Messel) include fruit remains and no insects. This is likely a real reflection of diet rather than a taphonomic artifact because in other Messel specimens insect remains preserve well (Franzen and Wilde 2003).
Cartmill (1972) attempted to counter this objection by arguing that features such as lower crowned teeth and a reduced stylar shelf, interpreted as being associated with a more herbivorous diet (Szalay 1968), do not “... contradict the hypothesis that the ancestral primates were primarily insectivorous” (Cartmill 1972 p 117). Although it is certainly very probable that early euprimates ate some insects, as do all modern small primates (Fleagle 1999), this observation is irrelevant for two reasons. First, the key information for assessing evidence for an evolutionary transition is not static reconstruction of diet but verification of a change in diet. Just demonstrating that early euprimates ate some insects is not sufficient—if visual predation is to be supported as an important formative force in euprimate evolution, a shift to greater insectivory must be demonstrated. Unambiguous evidence for such a shift is lacking from the fossil record.

Second, the relevant comparative sample for early euprimates is not living primates but contemporary insectivores. If early euprimates were succeeding and diversifying primarily because they were improving their insect-harvesting abilities, then they should show dental features that indicate that they were at least as well adapted for processing insects as insectivorous mammals living at the same time. This is not the case—most specialized insectivores from the Paleocene and Eocene have much higher crowned teeth and sharper cusps than early primates. It is precisely the absence of such features and the presence of characteristics for processing non-leafy plant material, such as low-crowned molars with broad talonid basins, which make it possible to separate primitive primate and insectivoran teeth in the fossil record. The insectivorans most similar to primates in dental form can be reconstructed as having a more omnivorous diet than their specialized insectivorous kin. For example, the erinaceomorph *Macrocranion tupaiodon* from Eocene deposits at Messel, which has superficially primate-like teeth, is known from stomach contents to have eaten not only insects but also plant material and substantial quantities of fish (Storch and Richter 1994).

The features suggesting a more herbivorous diet in early primates and euprimates are supportive of the angiosperm diversification hypothesis. Since fully euprimate-like pedal grasping pre-dates the origin of Euprimates, the pattern of acquisition of adaptive features does not match precisely the timing of events envisioned by Sussman (1991; Sussman and Raven 1978). Nonetheless, his main points do still have merit. The origin of the order Primates is associated with dental changes for increased herbivory (Szalay 1968). This was likely associated with specializations for terminal branch feeding, including grasping traits, in an omnivorous animal. Within various plesiadapiform lineages and early euprimate groups, improved features for exploiting plant propagative organs continue to appear through the Paleocene and Eocene (Gingerich 1976; Biknevicius 1986; Rose 1995; Bloch and Boyer 2002).
The one major shortcoming of the angiosperm diversification hypothesis is that it may fail to explain the rest of the distinctive traits seen in modern primates (i.e., visual features and leaping). Sussman (1991 p 219) did try to build an explanation for visual traits into his ideas by linking the manipulation of small food items in low light conditions and on tenuous substrates to a need for “acute powers of discrimination and precise co-ordination.” The lack of evidence in modern analogues such as bats for a solid link between frugivory and convergent orbits has led to this view largely being discounted (Ravosa and Savakova 2004). However, perhaps modern models, such as bats, are not appropriate for comparisons to early euprimates, who undoubtedly used a different feeding mode. As Crompton (1995 p 18, emphasis his) pointed out, euprimate visual traits may have evolved for their power in breaking crypsis (i.e., picking out camouflaged food items from the background), and as such could have been beneficial in allowing detection of the “small, and often very inconspicuous” food items taken by small primates. In terms of leaping, Rasmussen’s (1990 p 273) observations of Caluromys also offer a potential explanation for the value of this locomotor mode to a terminal branch feeder: “The grasping and leaping acrobatics exhibited by C. derbianus in Costa Rica enabled them to gain access to fruit that was apparently off limits to most of the other nocturnal frugivores of the study area.” Perhaps it was refinements to terminal branch feeding techniques, offering new access to previously inaccessible food sources and greater abilities for discriminating food choice, which marked the transition to Euprimates. This would only be a difference from Sussman’s scenario in the traits that are emphasized, not in the ecological events that were key.

Rasmussen’s combination hypothesis could be seen as offering an alternative to the angiosperm origins scenario that explains first the grasping and fruit-eating dental features of basal primates and then the visual characteristics of euprimates. However, this combination hypothesis suffers from the same problems as visual predation in linking the evolution of orbital traits to increased insectivory in the absence of evidence for such a dietary shift. On the basis of the current evidence, the angiosperm diversification hypothesis applies best to the evolution of early primates. Furthermore, Szalay’s (1968) view of the key event in primate origins being a dietary transition to a more plant-dominated repertoire is also supported by the current evidence.

1.3 Timing and place of origin of primates and euprimates

The earliest occurring primate known is Purgatorius, from either the latest Cretaceous (Van Valen and Sloan 1965; Van Valen 1994) or earliest Paleocene
Primate origins and supraordinal relationships: morphological evidence

(Johnston and Fox 1984; Lofgren 1995) of North America. Most of the rest of the early primate fossil record is North American, including all definitive micromomyids and palaechthonids, most microsyopids, and all the most primitive paromomyids, carpolestids, plesiadapids, and possibly saxonellids (Fox 1991). Plesiadapiforms have only been known from Asia since 1995 (Beard and Wang 1995), which suggests that this geographic bias may be a sampling phenomenon. However, the lack of Asian (or European or African) taxa as primitive as *Purgatorius* is supportive of a North American origin for the order Primates (Bloch et al. submitted).

In terms of the place of origin of Euprimates, Beard (1998) argued that it could be reconstructed as unequivocally Asian. We view this assertion as excessively confident. Silcox (2001) reached a very different conclusion, with origins in Asia, Africa, North America, or even Europe being possible in the context of the current record. Causes for this equivocation include the African location of the earliest known euprimate, *Altiatlasius koulchii*, the Asian location of the primitive euprimate *Altanius orlovi*, the North American location of much of the primitive plesiadapoid and euprimate record, and the European location of both some early euprimates (*Donrussellia*) and of the poorly sampled plesiadapiform family Toliapinidae, which may be related to early euprimates (Silcox 2001; Figure 1.4a).

The time of origin of the two major clades under discussion here (Primates and Euprimates) can only be minimally constrained using fossil data. As noted above, the earliest known primate, *Purgatorius*, is approximately 65 Myr old. In light of the primitive nature of this taxon, the fossil record is not consistent with a date much earlier than this, putting the origin of the group in the latest Cretaceous, somewhat later than even the most conservative molecular estimates (Springer et al. 2003). The earliest occurring euprimate, *Altiatlasius koulchii*, is Late Paleocene in age (Sige et al. 1990; Gheerbrant et al. 1998), implying a divergence for euprimates before the Early Eocene. Furthermore, since the sister group to Euprimates (i.e., Plesiadapoidea) had diverged from their common stem by the latest Early Paleocene, Euprimates must be at least that old.

1.4 Conclusions: what is a primate? (Coda)

When Cartmill developed the visual predation hypothesis, he suggested the removal from Primates of any taxa that lacked modern primate-like orbital and grasping features, and thus presumably had not used this mode of feeding (Cartmill 1972, 1974, 1992). This was the primary basis for Cartmill’s suggested removal of plesiadapiforms from Primates. Such an approach to defining Primates was perhaps an overoptimistic view of the support for visual predation—if,
as suggested here, an evolutionary transition to this pattern of behavior is not clearly indicated by the fossil record, then this is surely not an appropriate criterion by which to determine inclusion or exclusion of taxa in the order Primates. This view is underscored by the fact that of the three “ordinally diagnostic” traits that Cartmill (1972 p 121) named to diagnose a plesiadapiform-free order Primates—“... the petrosal bulla, complete postorbital bar, and divergent hallux or pollex bearing a flattened nail ...”—two are now known in plesiadapoid plesiadapiforms (Bloch and Boyer 2002, 2003; Bloch and Silcox 2006). The fossil record demonstrates that the characteristic primate traits listed in the introduction arose in a step-like fashion (Figure 1.5). Thus, the criterion that all of these features must be present in a particular taxon for it to be considered a primate is biologically unnatural. Doing so would exclude taxa on the primate stem who have some, but not all, of these traits, but who postdate the divergence of the primate lineage from the rest of Mammalia. As demonstrated above, such stem taxa are critical for understanding the origin and early evolution of Primates, as well as the accumulation and modification of crucial features within this lineage.

As advocates of phylogenetic taxonomy have made clear, there are some distinct advantages to formal taxonomic definitions that are based on specifying a particular ancestor rather than on a list of mutable characters (Rowe 1987; De Queiroz and Gauthier 1990; Silcox in press). For this reason, although compiling lists of distinctive primate traits is useful to the process of understanding primate origins, it is inappropriate to consider them formal definitions. Using the precepts of phylogenetic taxonomy, Silcox (in press) suggested the following definition for Primates: “the clade stemming from the most recent common ancestor of Purgatorius and Euprimates.”

New discoveries will almost certainly change our views on the early parts of primate evolution. There are a number of substantial holes in the fossil record for primate origins, which when filled may fundamentally shift our perceptions of primate evolutionary history. First, there is a sizeable spatial discontinuity in the fossils currently available. Plesiadapiforms have only been discovered in Asia in the last 10 years (Beard and Wang 1995). Since we consider Altiatlasius to be a euprimate, the only potential plesiadapiforms from Africa are the poorly known Azibius and Dralestes (Tabuce et al. 2004). For early euprimates, the few specimens of primitive forms known from Asia and Africa are suggestive of a much larger radiation that is almost completely unknown (Silcox 2001). Even in North America, the geotemporal patterning of the plesiadapiform and euprimate fossil records means that there are still substantial areas at crucial times that remain unsampled.
Second, some taxonomic groups are also undersampled. Two families of plesiadapiforms, Palaechthonidae and Toliapinidae, have the potential to be crucial to an understanding of early primate and euprimate evolution, but both are very poorly known. The best-known plesiadapoids are all relatively derived members of their respective families. In light of the important position of Plesiadapoidea, as the sister taxon to Euprimates, finding more, and more complete, primitive plesiadapoid specimens is vital (Boyer et al. 2004). Perhaps most importantly, a gap still exists between the known plesiadapiforms and the earliest euprimates. No known plesiadapoid has the morphology that would be expected in a euprimate ancestor—they are all too derived in features such as dental reduction, enlargement of the anterior-most incisors, and/or the shape of P4. Because the earliest plesiadapoids are late Early Paleocene in age, Euprimates must have a ghost lineage stretching through the Middle and Late Paleocene, which is entirely unsampled. Filling this particular gap will be central to clarifying the evolutionary and adaptive significance of traits for euprimate-like vision and leaping. In light of the complete absence of taxa to fill this gap from the comparatively well-sampled North American record, it seems most plausible that they were living in the Old World.

Finally, since understanding the supraordinal relationships of Primates is central to reconstructing events at the base of the order, a better fossil record for other euarchontan groups is also central to the problem of primate origins. As it stands, the Paleogene fossil record for scandentians and dermopterans is virtually nonexistent, with the exception of a single dermopteran specimen from the Eocene of Thailand (Ducrocq et al. 1992), fragments of scandentian teeth from the Eocene of China (Tong 1988), and plagiomenids, which may be fossil dermopterans. Furthermore, a better understanding of various other fossil groups for whom a tie to Archonta, or specifically to Primates, has been suggested (apatemyids, nycitheriids, mixodectids; Szalay and Lucas 1996; Hooker 2001; Silcox 2001; Silcox et al. 2005), has the potential to further clarify the evolutionary events downstream from Primates in the euarchontan evolutionary tree.

Although this discussion of holes in the fossil record may seem disheartening, the enormous progress that has been made in the last 10 years for our understanding of primate origins suggests we may not have to wait long for some of these holes to be filled. We have moved from a position analogous to that of early anthropologists arguing about whether brains or bipedalism arose first in human evolution, without having any relevant data to choose between the two, to being able to actually test hypotheses about the order of acquisition of traits in early primate evolution. We can only hope that continuing diligence on the part of researchers interested in primate origins will serve to fill some of these
gaps and allow us to continue expanding our knowledge of the earliest chapters in our own evolution.

Acknowledgments

2 Molecular Evidence on Primate Origins and Evolution

Hans Zischler

Abstract

Over the last decade, research on primate phylogeny has been of increasing interest to the scientific community. From the perspective of molecular evolution, this is mainly due to the fact that the mass generation of molecular sequences has become easy and cost effective. With the generation of complete sequences for several eutherian organisms including humans and the mouse, a well-accepted phylogenetic interpretation for all members of the Euarchontoglires and all major groups of the primate order is feasible and would represent a new starting point for meaningful comparative research. Such a phylogenetic framework would link humans with the mouse, which is generally regarded as the main eutherian model organism. Thus, our knowledge of primate origins and the evolution of primates is a prerequisite for a postgenomic era in which aspects of functional genetics and character evolution will form a focal point of genetic research. Despite the pace at which primate sequences can be generated in whole genome shotgun (WGS)-sequencing projects, primate origins as well as several branching events in primate divergence remain far from settled. First, complete primate genome sequences are currently available for two representatives of the Old World monkeys and hominoids and humans only. Information is lacking on the deeper primate splits and comparative data are restricted to parts of primate genomes (ENCODE project). Second, it is obvious that the peculiar mode of sequence evolution (including gene-, lineage-, and position-specific evolutionary rates), combined with deep splitting events that often occurred during small time intervals may possibly lead to incongruence between gene and species trees. To avoid this, it will be necessary to have enormous amounts of sequence data and the implementation of more realistic assumptions about sequence evolution models in sequence-based phylogenetic tree reconstructions. Moreover, alternative molecular approaches, including both the incorporation of data of so-called “rare genomic changes” (RGCs) and a combination of both neontological and paleontological morphological data in total evidence approaches, are likely to contribute considerably to a firm
interpretation on the origin and evolution of primates. Below I summarize and discuss molecular evidence obtained for the origin and evolution of pri-
mates, stressing the potential of the inclusion of “RGCs,” mainly retropositions of short interspersed nuclear elements (SINEs) in this context.

2.1 Introduction

2.1.1 Primate genetics in the postgenomic era

As the closest extant relatives of *Homo sapiens*, nonhuman primates have always been of particular interest in biological and biomedical research. With the advent of the first drafts of the complete DNA sequence of the human genome reported in 2001 by the IHGSC and Celera Genomics, the postgenomic era began, focusing on functional and diversity aspects of human DNA. With the complete genome sequence of the mouse, generally considered the most important eutherian model organism, the goal of pinpointing the evolutionary changes in the lineage to humans and of bridging the gap between eutherian model systems and humans has brought the order Primates even more into the focus of postgenomic evolutionary research. Obviously, the phylogenetic history of nonhuman primates forms a part of our own evolutionary history. Though each primate taxon represents the realization of a stochastic evolutionary process that occurred during primate divergence, tracing the genomic changes that can be identified by comparing different eutherian and primate taxa will shed light on the processes that can shape our genomes over evolutionary time scales. As with every analysis, e.g., of morphological, physiological, or behavioral character evolution, the latter requires an undisputed phylogenetic framework for discerning between homology and analogy. For that reason, this review will mainly summarize the molecular data and interpretations currently to hand on the origins and phylogenetic affiliations of primates and closely related eutherian orders. Although a complete appraisal of the respective available information would clearly go beyond the scope of this review, molecular evidence on the divergence of the main primate groups will be discussed. Though a major research focus that is attracting enormous public interest is the understanding of human uniqueness, Goodman et al. (2005) correctly stated that this understanding cannot be complete if we look exclusively at the (molecular) differences between humans and their phylogenetically closest primate relatives. To fully comprehend human uniqueness, we need to understand how humans differ from chimpanzees, how great apes differ from the remaining haplorhines, how strepsirhines are set apart from the latter, and how primates differ from other eutherians.
A special emphasis will be given to a type of marker system that allows a molecular cladistic approach to determine sister group relationships by analyzing rare genomic changes (RGC) such as insertions of retroposons with respect to their presence or absence in certain taxa. Though focusing on the molecular cladistic information of these sequence changes, it has to be kept in mind that they might exert an effect on the respective transcriptomes and proteomes.

Although mainly molecular evidence will be presented in this review, it must be kept in mind that paleontological and neontological morphological data are urgently required to complement the molecular database and to establish a “total evidence” phylogenetic framework. This will in turn enable us to trace character evolution during the emergence and divergence of primates. Remarkably, the overall congruence of phylogenetic interpretations based on the two sources of data is substantial, offering the prospect that total evidence approaches will soon lead to a broadly accepted hypothesis on the eutherian phylogenetic affiliation, origin, and evolution of primates.

2.1.2 Eutherian evolution: molecular data and problems

Until the advent of cost-effective generation of molecular data, research on mammalian phylogeny was essentially dominated by morphological and paleontological approaches.

Recently, Novacek summarized a consensus tree from these analyses that had its roots in the influential work of Gregory and Simpson dating back to the beginning and middle of the last century. It has, however, to be stressed that many of the phylogenetic constellations proposed therein were and are still matters of debate among paleontologists and morphologists. On the basis of the classical approach, Xenarthra (e.g., armadillos, anteaters) constitutes the most basal placental group, with the remaining eutherian orders comprising the Ungulata, Anagalida, and Archonta. The latter group or superorder comprises the orders Scandentia, Dermoptera, Chiroptera, and Primates. Over a decade ago, sequences for complete mitochondrial genomes became available, adding molecular evidence to a discussion that formerly had exclusively dealt with interpretations based on nonmolecular data.

After the draft human genome sequence was completed in 2001, plans to expand whole genome shotgun (WGS) sequences to other mammalian species were proposed and projects initiated. Besides the complete human, chimpanzee, and rhesus monkey sequences, other non-primate and primate representatives including the bush baby, the common marmoset, and the tree shrew are about to be sequenced completely (a constantly updated list of the sequencing proposals
and projects can be viewed under http://www.genome.gov/10002154). In addition, sequencing projects, especially the encyclopedia of DNA-elements-project (ENCODE project, Encode Project Consortium 2004), aim to create a large set of comparative data mainly from functional regions of the genome. Numerous taxa are in the pipeline for partial sequencing to be carried out from bacterial artificial chromosome (BAC) clones already available for a rather representative set of primate taxa (see http://bacpac.chori.org/). A large-scale comparative sequencing of the cystic fibrosis transmembrane conductance regulator (CFTR) locus region can be regarded as an initial example of such an undertaking (Thomas et al. 2003). Thus any deficiencies in the molecular data, mostly involving taxonomic representation and suitability for eutherian phylogenetic analyses, are likely to be erased in the foreseeable future. Initially, phylogenetic interpretations of complete mitochondrial DNA (mtDNA) from different eutherian taxa led to various unorthodox phylogenetic proposals, provoking a debate about the appropriateness of mtDNA-based eutherian phylogenetic tree reconstructions or even molecular approaches in general. However, over the last years a molecular consensus has been emerging, with a topology that deviates in essential aspects from the morphological tree, due to an improvement of bioinformatic tools that incorporate more detailed knowledge of sequence evolution models. Second, the flood of incoming sequence data—mainly from the nuclear side—is overcoming the major early problems of molecular studies, namely an incomplete and unbalanced taxon sampling combined with limited sequence information from short DNA alignments. Recent compilations of extended molecular data sets suggest three novel superordinal clades, and that extant eutherians can be partitioned into four major groups, the Laurasiatheria, Xenarthra, Afrotheria, and Euarchontoglires. This grouping emerged at a 1999 meeting (Waddell et al. 1999) and was corroborated in several subsequent studies (Madsen et al. 2001; Murphy et al. 2001a, b). The Euarchontoglires comprise lagomorphs and rodents on the one side and the scandentians, dermopterans, and primates on the other. Interestingly, both mtDNA and nuclear DNA (nDNA) analyses reproducibly exclude the chiropters from the Euarchontoglires, suggesting a closer affiliation of chiropters to, e.g., cetartiodactyls than to primates. As to phylogenetic affiliations inside the Euarchontoglires, the rodents and lagomorphs are considered to represent sister groups. But the phylogenetic affiliations among the remaining members, the primates, flying lemurs (Dermoptera), and tree shrews (Scandentia) remain highly disputed. Solid support for these superordinal groups has come from independent studies of the substitutional evolution of nuclear genes and complete mtDNAs. Many of these studies may be hampered by reconstruction problems due to position, gene, lineage-specific evolutionary rates, uneven nucleotide compositions, and inadequate taxon sampling. In fact, powerful
molecular cladistic information can be found in RGCs that convincingly corroborate the four eutherian clades (Springer et al. 2004; Kriegs et al. 2006). Mainly because point mutations can be regarded as weak, homoplasy-prone characters, the recognition of multiple phylogenetic characters including RGC has gained increasing popularity in phylogenetic research.

Under the umbrella of RGC, an assemblage of completely different molecular scenarios is found. These include indels in protein coding regions—an RGC that supports the Euarchontoglires-clade—as well as changes in gene order and intron position, large-scale rearrangements and duplications, and finally the existence and distribution of transposable elements in different genomes.

It has to be stressed that our current knowledge on the different DNA turnover mechanisms that stand behind these phenomena is very variable. Hitherto, probably the best understood RGC is represented by the transpositional activity of repetitive DNA. Due to the abundance of these potential marker systems in typical metazoan genomes, it is currently the most widely applied RGC and will be presented in more detail below.

2.1.3 Problems relating to primate origins and phylogenetic affiliation to other eutherians

From a paleontological point of view, the definition of primate origins and separation of proto-primates from closely related eutherians is not a trivial task. First, there are no very specific morphological fossil features that can unify all primates. Not taking molecular data into account, primates are characterized by a long list of common morphological features given by Le Gros Clark in 1959 and supplemented by Napier and Napier (1967). Superficially, this list of primate features should enable researchers to clearly define an individual that belongs to the primate order. However, there is no unique morphological, physiological, or behavioral character that clearly characterizes a primate. The criteria mentioned in the references above rather represent a collection of symplesiomorphic features and do not contain an undisputed synapomorphy defining a clade. Many “typical primate” features are either behavioral or depend on soft tissue anatomy, so deciding whether this or that fossil represents a primate is notoriously difficult.

Second, the scanty fossil record of early primates represents a major problem for studying the origin of primates. Tavaré et al. (2002) suggest that the currently available fossil record only shows 7% of all primate species that ever existed. They estimated that the common primate ancestor existed about 81.5 million years ago (Ma), which is considerably older than previous estimates based, e.g., on paleontological evidence. For the latter, Purgatorius—a taxon that lived in North
America and Eurasia at least 65 Ma during the Late Cretaceous and Early Paleocene—was hitherto regarded as the prime candidate on which all extant primate species coalesce (Shoshani et al. 1996).

Another complicating factor is represented by growing evidence that archaic primates or Plesiadapiformes are much more diverse than previously assumed. Various phylogenetic constellations have been proposed and are still being discussed for the different plesiadapiform families and extant members of the euarchontan orders. Molecular data obtained from extant taxa might thus complement this discussion by enabling hypotheses on the phylogenetic affiliations between primate and non-primate crown groups.

Before I review the available molecular information on primate origins, it is necessary to provide some information on retroposable DNA sequences. Evidence from this type of RGC is currently used to corroborate phylogenetic interpretations based on the analysis of substitutional sequence evolution. To estimate the probability of homoplasies and reversals and to assess the value of this molecular cladistic marker system, some basic knowledge of the biology of retroposing DNA is necessary.

### 2.2 Molecular biological approaches and methods

#### 2.2.1 Genetics of retroposons

As in other eutherian mammals, primate genomes harbor a variety of repetitive sequences with no obvious and global function (Smit and Riggs 1995). The bulk of these discernible sequences, constituting more than 40% of the human genome (Li et al. 2001), represents remnants of molecules that were mobilized during the evolution of extant species. This number is even likely to be an underestimate of the repetitive sequences in primate genomes, since sequence evolution might eradicate signatures of formerly repetitive DNA of extinct taxa. More WGS sequence data from primates are needed before we can conclusively answer the question of the quantity of each specific repetitive sequence in a certain taxon.

Sequences that belong to class II elements can be mobilized by a cut and paste mechanism involving a DNA intermediate, while class I elements transpose replicatively by a copy and paste mechanism via an RNA intermediate (retro-elements). Class I, or retroelements, decoding their own reverse transcriptase, allows an autonomous transposition. This group includes the non-LTR (long terminal repeat) elements such as long interspersed elements (LINEs) decoding two proteins, an RNA-binding protein and an endonuclease/reverse transcriptase, and LTR elements as well as the true retroviruses (Hedges and Batzer 2005).
Short interspersed elements (SINEs) form another type of class I element with nonautonomous transposition, exploiting instead the enzymatic retropositionary machinery—proteins with reverse transcriptase and endonuclease activity—of other elements such as LINEs. SINEs are the most abundant class I sequences to be traced in primate genomes. Typically, SINEs range between 75 and 500 bases in size and may be amplified to a copy number well beyond $10^4$ total copies per genome. The majority of the eukaryotic SINE families described so far can be traced back to a tRNA ancestor, with a minority apparently derived from 7SL RNA. A common feature of both types of SINEs is their internal promoter that is specific for RNA polymerase III (Okada 1991a, b). The most abundant SINE in primates is represented by the so-called Alu-SINE, which evolved from a 7SL RNA.

Further actively retroposing sequences are represented by the LINE retroposon family. Considering the length and copy number of LINEs, these sequences represent the most abundant sequences in the human genome. Primate L1 sequences amount to roughly 6,000 bp in length, containing an RNA Pol II promoter, two ORFs, a 3′ UTR, and Poly-A tail. An RNA-binding protein is decoded in the first ORF; the second ORF codes for an endonuclease and reverse transcriptase. Of more than 800,000 estimated L1 copies in the human genome, most of the LINEs in hitherto sequenced primate genomes are 5′ truncated (and therefore also lack the capacity of further retroposition). Thus close to 10,000 copies are full length and about 100 are active for retrotransposition in a tissue culture assay. It is estimated that over one-third of mammalian genomes are the result, directly or indirectly, of L1 retrotransposition (Han and Boeke 2005). Integration of non-LTR retrotransposons, such as mammalian L1 and related SINEs (e.g., Alu sequences), is mediated by the mobilization machinery from LINEs represented in the two LINE–ORFs decoding an RNA-binding protein and an endonuclease/reverse transcriptase, respectively.

During SINE/LINE retroposition, the RNA intermediate is reverse-transcribed by a process called target-primed reverse transcription (TPRT) (Luan et al. 1993; Feng et al. 1996; Jurka 1997; Kazazian and Moran 1998; Kajikawa and Okada 2002). Here the endonuclease cuts the target DNA at two nicking sites, creating a staggered end break of the double stranded target DNA. This staggered end break is subsequently filled and is recognizable as a direct repetitive sequence flanking the integrated element.

Bioinformatic analyses of these direct repeats, representing the target sites, suggest that from the two nicking sites of this machinery only the 5′ site is relatively conserved in contrast to the 3′ site. Furthermore, it is not understood which factors affect the cleavage at the second site and how specific this process is for different combinations of SINEs and LINEs. Taken together, this is indicative
of the uniqueness of a single LINE-mediated retroposition even over evolutionary
time scales (Zingler et al. 2005).

As is the case for Alu-SINEs, also L1 sequences are obviously to a greater
extent mobilized in the germline, with a possible bias toward the male germline.
This phenomenon is currently seen as a consequence of the host defense toward
transpositional activity, which is mediated by the methylation of DNA. In the
course of germ cell development demethylation takes place, allowing increased
transpositional activity (Hedges and Batzer 2005).

Besides Alu sequences and L1 that altogether constitute more than 30%
of the human genome, other TE are still actively retroposing in primate
genomes and can be traced in high copy number in primate genomes. Prominent
SINE examples are the tRNA-derived galago monomer (Daniels and Deininger
1991) found in all lorisiform species analyzed to date (Roos et al. 2004) and
type II SINEs, the latter representing a SINE composed of both tRNA- and 7SL-
derivatives.

Further primate TE types include DNA transposons, SINE-R, LTR retro-
transposons, and endogenous retroviruses (ERVs). Apparently, a DNA transpo-
son TIGGER gave rise to smaller miniature inverted repeat transposable elements
(MITEs) sequences in an ancestral primate. Their exact quantitative contribution
to extant primate genomes remains to be determined. However among the
Euarchontoglires, DNA transposons that mobilize by cut and paste mechanisms
are apparently more commonly found in rodent genomes (Hedges and
Batzer 2005).

ERVs or remnants of them that still reside in primate genomes represent the
outcome of germline retroviral infections that took place at various time points
during primate divergence. In humans these ERV sequences constitute about 1%
of the genome. There are several lines of evidence that ERVs can alter the
expression pattern; their impact on the primate genomes was recently summa-
ized by Sverdlov (2000).

Finally, a composed element—the SVA repeat comprising Alu-like, SINE-R
and VNTR elements—is sometimes mentioned as a still active retroelement. As
among Alu-SINEs, the SVA is dependent on L1 mobilization factors. Both
chimpanzee and human genome analyses reveal that this element is still active
and also disease related. Obviously, not all types of repetitive DNA elements are
still mobilizable. The most prominent example in primate genomes is represented
by the mammalian wide interspersed repeats (MIRs). These MIR sequences are
highly divergent, suggesting a deep coalescence. Indeed, the vast majority of
active MIR sequences was actively transposing during early mammalian evolu-
tion, representing a shared ancestral character state among all eutherians (Hedges
and Batzer 2005).
2.2.2 SINEs as cladistic markers

Much research has been directed at the biology, genetics, and the genome-shaping as well as functional implications of retroposable elements. Retrotransposition-mediated deletions, gene conversion, or SINE-mediated recombination events that trigger further large-scale genomic rearrangements are known as directly shaping primate genomes. Furthermore, SINEs have repeatedly been shown to display a gene regulatory function from the epigenetic level to their role as possible modifiers of splicing events. Mobile elements are capable of moving around regulatory sequences for different transcription machineries as well as unrelated sequences 3′ to the repeat element—a process called transduction. Repeats can be exapted as functional parts of newly invented proteins thus exerting an effect on the proteome.

As temporal landmarks of evolution, SINEs and LINEs have also gained widespread application in evolutionary biology. This type of cladistic analysis ideally complements sequence-based phylogenetic reconstructions. Whereas the latter ideally allow us to make inferences about the timing of splitting events by comparing the distances between certain taxa, the former complements conventional sequence analyses from a completely different perspective.

Theoretically, a SINE/LINE analysis can be done on both the multilocus and single locus levels. The former can be done in a technically easy hybridization experiment and does not require any sequence information apart from the SINE/LINE sequence itself. As far as a SINE with a high copy number in a certain taxon to the exclusion of another is concerned, the pure presence/absence pattern can be informative about phylogenetic affiliations and unite all subtaxa belonging to the former into a monophylum. For the monolocus approach, sequence information from the region surrounding the integration is necessary to design primers that specifically amplify the orthologous regions in the taxa under scrutiny.

Molecular cladistic SINE/LINE analyses are becoming widely used since they are regarded as representing powerful noise-free Hennigian synapomorphies (Shedlock and Okada 2000).

The latter is due to the fact that SINEs/LINEs as marker systems in evolutionary biology display rates of homoplasies and reversals that can be safely assumed to be far lower than observed for sequence data and complex morphological characters. As far as the relatively unspecified targets of the LINE integration machinery (see above) and the size of a typical eutherian and primate nuclear genome are concerned, the chance of SINE/LINE integrations independently involving the same targets is negligible even over evolutionary time scales. Although, e.g., repeats may preferentially integrate into locally AT-rich regions in
chromosome R bands (Korenberg and Rykowski 1988; Matera et al. 1990) or might have a tendency to prefer integration into DNA regions that can adopt alternative structures, for instance kinks, the LINE machinery does not have a constant and unambiguous integration site that can be specified by comparing the SINE/LINE flanking direct repeats. Even if a closely spaced target site has been hit in different evolutionary lineages by an integration event, the direct repeat and the structure and characteristics of the SINE/LINE itself can give precious information on the true orthology of SINE/LINE integrations. SINE/LINE insertions, present at the orthologous positions in different genomes, can thus reliably be considered to be identical by descent.

A further huge advantage of SINE/LINE integrations compared to sequence data is the virtual absence of homoplasies resulting from character reversals. Although evidence was recently reported, after comparing complete human, chimpanzee, and rhesus monkey sequences, that in rare cases a certain SINE can be precisely reexcised, creating a situation similar to the incomplete lineage-sorting process mentioned below (van de Langenmaat et al. 2005), the rate of integration-reversals must be lower by orders of magnitude than the rate of substitutional reversals. Thus in primates, contradictory results among individual presence/absence analyses that need to be generated if reversals occur at decent frequency were simply not observed in the analysis of hundreds of different orthologous Alu-SINE integrations involving the different primate infraorders. Compared to the vast bulk of the molecular cladistic information of a certain branching event in question, a precise reversal would be either not remarked at all or clearly recognized as an autapomorphy.

Of course, major parts of chromosomes can be deleted during the course of evolution and might encompass SINE/LINE sequences. However, a molecular cladistic analysis can discriminate between the absence of an orthologous SINE/LINE and the absence of the respective stretch of DNA. In a typical experiment, PCR primers need to be placed well away from the SINE/LINE and should incorporate some single-copy flank. A shorter PCR fragment thus signals the absence of a SINE/LINE, a longer fragment its presence. A deletion of the SINE/LINE and flanking regions would not generate any PCR fragment. Thus, the presence of a SINE insertion yielding a PCR fragment that is longer than the insertion absent-fragment reflects the derived character state. An unoccupied target site or shorter PCR fragment that—depending on the age of the very integration—can be easily diagnosed by the presence of the short repeat-flanking sequence in an unduplicated version represents the ancestral character state. This in turn results in a well-defined character polarity of these molecular cladistic markers. Naturally, SINE-based molecular cladistic analyses do have some limitations that might be overcome by applying different experimental strategies.
One problem is that most SINEs are located in noncoding regions, which usually display considerable divergence when analyzing taxa that coalesce deeply. In consequence, PCR primers might not possess sufficiently conserved targets to allow efficient amplification across highly divergent taxa. Schmitz et al. (2001) developed a strategy and used intronic SINEs as markers that allow the construction of primers that target into conserved exonic regions, thus amplifying the encompassed intron together with the SINE. This strategy can even help to manage interordinal amplification problems.

Another problem, which affects every polymorphic marker system, is the uneven distribution of ancestral polymorphisms into progeny lineages. This phenomenon is termed incomplete lineage sorting and affects very recent splits as well as deeper, consecutive splitting events that took place within a short period of time. It is obvious that every derived character state is the result of a mutation (or integration) that happened in the germline of one individual of a certain taxon. This mutation will be enriched in the succeeding generations but might not reach fixation. If ancestral polymorphisms are incompletely sorted into progeny lineages, gene trees might deviate from species trees. The fixation of a neutral polymorphism (one can safely assume that many SINE/LINE integrations, e.g., in noncoding regions, do not have a functional consequence) is dependent on the effective population size. Since the effective population sizes accompanying a splitting event are mostly unknown, it is difficult to determine whether a SINE marker was fixed in the ancestral progenitor population at the base of the consecutive split. It is therefore of great importance to collect split-specific SINE information at multiple independent loci in order to test for any inconsistencies in marker interpretations that might have been caused by lineage sorting (Takahashi et al. 2001). The WGS data currently at hand, and those produced in the near future, will allow us to define such a large number of markers that it should be easy to avoid errors caused by lineage sorting.

2.2.3 Molecular evidence of primate origins

Currently, inferences based both on conventional sequence analyses and RGC support the existence of a Euarchontoglires-monophylum in that Primates and Glires are assembled together with dermopterans and scandentians. Thus, the two eutherian orders Dermoptera (flying lemurs) and Scandentia (tree shrews) are noted as potential extant sister groups to the primates, although another construction would be that both are united as sister groups, branching off before the divergence of primates. Molecular evidence—both nuclear and mitogenomic—points overwhelmingly to an exclusion of bats from the Euarchontoglires (Pumo et al. 1998;
Teeling et al. 2000). The supposed close phylogenetic relationship between Dermoptera and Chiroptera might therefore be based on convergences that emerged with the evolution of gliding or flight.

From a molecular point of view, only contradictory information is available on the position of the scandentians. This is due to the fact that hitherto only limited phylogenetic information could be gained from short alignments and somehow unbalanced data sets. Moreover, there is growing evidence that the inclusion of mtDNA sequences in the analysis of the major primate groups and primate-related eutherian orders is linked to obtaining contradictory results. Starting from sporadic observations related to the proposed close affiliation of dermopterans to anthropoid primates (Arnason et al. 2002), initially Schmitz et al. (2002a, b), Schmitz and Zischler (2003), and recently Raina et al. (2005) proposed that there are several evolutionary jumps related to the nucleotide composition of mtDNA of primates and related eutherian orders. As the cause of this, the latter proposed the asymmetric and asynchronous replication mode of mtDNA, involving two different origins for the two different DNA strands, since the replication is started at different time points. This “classical” mechanism of mtDNA-replication is probably the one that usually takes place, leaving considerable parts of the mtDNA in a single-strand configuration over longer periods during the replication. During single-strand configuration, DNA is prone to hydrolytic damage, namely deamination of cytosine and adenine, causing transitions to thymine and guanine, respectively. The resulting changes in the overall DNA composition might therefore lead to unorthodox and artifactual phylogenetic affiliations caused by similar base compositions rather than emerging from true phylogenetic information. Most unexpected to primatologists was the close affiliation of dermopterans to anthropoid primates, which was proposed from a composed mtDNA and nuclear data sets (Murphy et al. 2001a) and from complete mtDNA information alone (Arnason et al. 2002). The term “Dermosimii” was even introduced to emphasize the close phylogenetic relationship between anthropoid primates and the dermopterans. Raina et al (2005) speculate that for similar reasons the position of Tupaia in the eutherian tree cannot be correctly determined on the basis of mtDNA sequence comparisons.

Finally, the hitherto underappreciated diversity of the scandentian taxa might pose another problem for inferring the correct phylogenetic affiliations of primate-related eutherians. Olson et al. (2005) correctly state that traditional interordinal studies, both morphological and molecular, often included only a single species of tree shrew. It is conceivable that by not adequately representing scandentian diversity, phylogenetic artifacts can also be created by the molecular approaches. Molecular data now at hand favor a scandentian monophyly and a sister group relationship between Ptilocercus and the remaining scandentian
genera. The phylogenetic relation to primates remains unclarified by conventional studies of substitutional sequence evolution.

What about the information obtained from repetitive DNA? Several Euarchontoglires representatives display SINEs in their genomes that are obviously derived from 7SL RNA, an RNA polymerase III transcript that constitutes the RNA part of the signal recognition particle. These include the rodent B1, the primate Alu-SINES, and the scandentian Tu type I and II SINE families (Nishihara et al. 2002). No 7SL RNA-derived SINE family has yet been detected in rabbits or flying lemurs. The lagomorph genome harbors a SINE family designated the C repeat (Cheng et al. 1984), the latter however is presumably derived from tRNA genes (Sakamoto and Okada 1985). Schmitz and Zischler (2003) and Piskurek et al. (2003) characterized tRNA-derived elements in the flying lemur genome. These tRNA-derived elements apparently constitute the major class of SINEs in these genomes; however they cannot be traced in primate or scandentian genomes. This is corroborated by the fact that the respective paralogs display only little divergence, suggesting a coalescence to a recent ancestor. At any rate, from an alternative molecular perspective these elements separate dermopterans from the other Euarchontoglires.

As far as possible SINE information for the scandentian affiliation with other eutherians is concerned, it is interesting that both scandentian and some strepsirhine primate taxa belonging to the lorisiforms harbor a compound SINE in their genomes. The latter is composed of both a 7SL and a tRNA-derived SINE (Tu type I and II and the galago type II element, Nishihara et al. 2002). 7SL RNA is also known as the precursor of the major primate SINE the so-called Alu sequences. Primate Alu elements display a dimeric makeup that originated from a fusion of the left and right monomer (FLAM and FRAM). An even more ancient monomer unit that forms part of the Alu family was named FAM (Quentin 1992a, b, 1994). Because of the similarity of the FLAM sequence to a precursor sequence of the rodent B1 family, it can be hypothesized that the precursors of primate Alus, rodent B1, and scandentian Tu elements, the FLAMs and FAMs might have been created in an Euarchontoglires ancestor. This would imply that these monomers were transpositionally active during these times. However, these monomer sequences have not been directly observed in the genomes of tree shrews or flying lemurs, an observation which might be also explained by sequence divergence that took place in the long and independent evolutionary history of the Euarchontan orders. A substantially different initial copy number and/or activity state of these elements after speciation is another possible explanation.

Until the first WGS data on a scandentian representative are released, it needs to be stated that 7SL-derived SINEs can probably not be used for
establishing sister group relationships among the different Euarchontoglires on the monolocus level.

However, SINE-data can also be used to separate the primates from the other Euarchontoglires. This can be technically easily done on the multilocus level. Dermopterans, misplaced by mtDNA analyses, can be firmly excluded as closely related to anthropoid primates as Arnason et al. (2002) suggested. The most abundant SINE in primates, the Alu-SINE which has about a million copies in the human genome, cannot be traced in dermopterans. If, as suggested by mtDNA analysis, the Dermosimii clade were correct, a simultaneous elimination of hundreds of thousands of Alu copies from the genome of dermopterans once they had split off from the lineage leading to the ancestor of anthropoid primates would have been necessary. This scenario can be firmly excluded.

Finally, a set of three monolocus repeat markers that are shown by representatives of all primate infraorders to the exclusion of other, non-primate eutherians including the Dermoptera (Schmitz et al. 2002b, 2003) can be defined, thus corroborating primate monophyly from a retropositional site.

Figure 2.1 summarizes the molecular evidence on Euarchontoglires obtained from retroposons. It can merely be stated that scandentians, dermopterans, and primates each represent monophyletic groups. Their firm consecutive splitting needs to await more data—the anticipated Tupaia WGS sequence will be one step in the right direction.

2.2.4 Infraordinal primate phylogeny

During the last decade, the number of primate species recognized has constantly increased. Even traditional classifications (Rowe 1996) included more than 230 species in this order, but nowadays well beyond 350 different species have been proposed (Groves 2001). Intensified field work, as well as the incorporation of molecular analysis, led to this large number. We may assume that in the foreseeable future, molecular data will reveal that current species diversity estimations for the extant primates are very conservative and that morphology-based classification has underestimated the genetic diversity. Primates may be traced back to a common ancestor—several authors quote Purgatorius as a possible candidate for the primate MRCA. The time of primate origin has constantly shifted backward over the last few years. Tavaré et al. (2002) proposed a time of 85 Ma based on paleontological evidence, and molecular data also tend to shift the MRCA further back in time than formerly thought. The origin and remarkable diversification of primates, rendering it one of the most successful eutherian orders, is usually
linked to three different theories: the arboreal theory, the visual predation theory, and the angiosperm radiation theory. Several aspects of these theories are constantly disputed, among them the general acceptance of the first primate ancestors being relatively small animals (Soligo and Martin 2005), a statement for which neither paleontological evidence nor extant taxa provides evidence. In addition, molecular data on the genes involved in color vision cannot rule out that trichromatic color vision was already present in the primate stem lineage, ruling out that nocturnality in primates is an ancestral character state (Tan and Li 1999;
Jacobs and Deegan 2003). Primates evolved full stereoscopic vision, reflected in the orbital convergence of early primates. In parallel, the olfactory system was reduced, mirrored in the reduction of the snout and the brain areas involved in the processing of chemosensory information. The number of functional genes for both taste and olfactory information was reduced during primate divergence and on the lineage to the hominoids. The increase in frequency of nonfunctional pseudogenes might be due to reduced selective pressures (reviewed in Hacia 2001).

In contrast to the uncertain interordinal phylogenetic relationships of primates with other extant eutherian representatives, far less disagreement exists about the phylogenetic affiliations between and within the major extant primate groups. The molecular data, mainly SINE evidence, are discussed below.

Obviously, by just taking the pure number of possible markers into account, the most abundant primate SINES, the Alu sequences, represent an inexhaustible source of molecular cladistic markers. However, it needs to be mentioned that all other sorts of retroposons can be taken as marker systems as well. ERVs, the remnants of ancestral germline infections by retroviruses, might serve as an example (Sverdlov 2000). However, the technical ease and speed at which Alu-markers can be established from WGS data of humans, chimpanzees, and rhesus monkeys—not mentioning the taxa for which WGS data will soon be available—have brought them into center stage in the molecular cladistics of primates.

Over one million Alu sequences have been identified in the human genome, thus comprising more than 10% of its overall sequence (Li et al. 2001). Alu-SINES can be traced back to a fusion of two monomers that took place in an ancestor of the extant primates. The resulting 300 bp element colonized primate genomes exclusively, thus representing a molecular synapomorphy that separates primates from non-primate species. Reliable estimates for Alu copy numbers in other primate species need to await more WGS data, but great apes and strepsirhine representatives are estimated to harbor several hundred thousands of Alu copies in their genomes as well. Alu sequences are frequently found in noncoding regions such as introns, untranslated regions of genes, and intergenic genomic regions (Deininger and Batzer 1993; Makalowski et al. 1994).

Alu sequences harbor diagnostic mutations that permit partitioning them into different subfamilies. This is assumed to be due to the fact that only a small subset of Alu elements was retropositionally active for a certain time period during primate divergence, thus serving as an Alu-source or “master” gene (Deininger et al. 1992).

Two contrasting models of SINE evolution have been linked to the retropositional activity of offspring SINES. A few active “master” SINES that are
capable of retropositional amplification are invoked by the master gene hypothesis (Deininger et al. 1992), whereas the “multiple source gene model” predicts that the progeny SINE copies can potentially propagate to the same extent as the parent SINEs they are derived from (Schmid and Maraia 1992). Experimental and bioinformatic evidence currently favors the “sprout” or multiple source model (reviewed in Shedlock and Okada 2000; Piskurek et al. 2003).

Alu-source genes thus accumulate diagnostic new mutations that give rise to a set of Alu subfamilies retroposed in chronological order (Batzer et al. 1996). Some of the young Alu elements described for humans, chimpanzees, and baboons have been integrated at their genomic location so recently that they have not become fixed in the respective taxon (Batzer and Deininger 1991; Perna et al. 1992; Batzer et al. 1994). Interestingly, active Alus are predominantly mobilized in the germline, with a bias toward the male germline. Probably epigenetic modifications are erased for a short time period during sperm cell development, inducing an increased retropositional activity of Alu-SINEs (Hedges and Batzer 2005).

The application of a molecular cladistic SINE analysis in primate evolutionary biology was first suggested by Ryan and Dugaiczyk (1989). However, the Okada group, working on different organisms, was the progenitor of the use of SINEs in molecular phylogeny in general. A short description of the current state of SINE-related phylogenetic research within the primates is given below.

A comprehensive SINE analysis of the strepsirhines is now to hand, giving a well-supported answer to long-standing phylogenetic questions related to the deepest primate split (Roos et al. 2004). Members of the strepsirhines constitute ca. 20% of all living primate species and can be subdivided into two groups, the Malagasy Lemuriformes and the Lorids found on the two continents Africa and Asia. Distribution of extant strepsirhines and paleocontinental reconstructions suggest an African origin of strepsirhines with two subsequent migrations to Madagascar and Asia. An oceanic barrier separated Madagascar from Africa and the Indian subcontinent from at least 165 and 88 Ma, respectively; thus even accepting the oldest dates for a primate origin would require the crossing of a huge water barrier. Both the timing and the physical crossing of the Mozambique channel from Africa to Madagascar remain much disputed. A long-standing question is therefore how often Madagascar was colonized by lemuriform ancestors. Molecular cladistic data could assist in answering this question by giving an unequivocal proof of the monophyly of Malagasy lemurs, suggesting a single colonization event.

A question usually formulated as a phylogenetic problem is related to the questionable cheirogaleid-galagid affiliation, based on the intracranial blood supply shared by both the Malagasy cheirogaleids and the African galagids.
The resulting tree topology would support at least two independent colonizations of Madagascar. Another problem regarding the monophyly of Malagasy lemurs is far more complicated and concerns the position of the aye-aye (*Daubentonia madagascariensis*). MtDNA data are not able to yield conclusive evidence for the aye-aye’s position and its relation to other Malagasy lemurs. Alternative topologies have been proposed, showing the aye-aye at the base of all strepsirhines, joined with the Indriidae, or not fully resolved with respect to other strepsirhines (Arnason et al. 1998).

A comprehensive analysis of strepsirhine phylogeny applying molecular cladistic markers was presented by Roos et al. (2004; Figure 2.2). By combining both multilocus and monolocus SINE evidence, SINE integrations were positive for a monophyly of Malagasy lemurs, with *Daubentonia* being a descendant of the deepest split and ruling out a close phylogenetic affiliation of cheirogaleids and galagonids. SINE-RGCs support Lorisidae as a monophyletic sister clade to the Galagidae and corroborate a common ancestry of African and Asian lorisids. Furthermore, one SINE integration links the two diurnal or cathemeral

![Figure 2.2](image-url)

**Figure 2.2**
Phylogenetic affiliations of extant strepsirhine representatives. The tree topology was taken from Goodman et al. (2005) and the number of molecular cladistic arguments (SINE insertions as RGC) displayed above the branches they support (Roos et al. 2004). The genera *Euoticus* and *Indri* were not included in the SINE analysis (in gray). The position of *Euoticus* could not be unequivocally determined by comparative sequence analysis.
lemuriform families, the Lemuridae and Indriidae, indicating an autapomorphic reversal to nocturnality by the indriid genus *Avahi*.

On the intraordinal taxonomic level, the most striking cladistic problem concerning the phylogenetic pattern of extant primates is represented by the phylogenetic affiliations of *Tarsius* to other extant primates. Differing taxonomic categorizations—the prosimian/simian and strepsirhine/haplorhine distinctions—reflect the uncertainty concerning the tarsier’s position in the primate phylogenetic tree. Its position is not easy to determine from molecular approaches since *Tarsius* is the only surviving genus of a formerly diverse group of Eocene tarsiiforms. Thus, this one genus cannot properly reflect the complete tarsiiform diversity that once existed. Moreover, the long independent history of *Tarsius* and its high likelihood of acquiring autapomorphies might confound phylogenetic tree reconstructions.

From a molecular perspective, mtDNA data are notoriously difficult to interpret, giving rise to artifactual assemblages based on mtDNA comparisons. First, deviations from a purely neutral mode of mtDNA-evolution were invoked to explain this apparent misplacing (Andrews et al. 1998). However, the unexpected positioning of *Tarsius* in an mtDNA-based phylogenetic tree could equally be explained by a base composition plasticity of mtDNA (Schmitz et al. 2002a, b; Raina et al. 2005). In contrast to mtDNA, most nDNA data sets firmly place *Tarsius* as a sister to the anthropoid primates, thus supporting the haplorhine grouping. SINE evidence on *Tarsius* has so far been obtained by both substitutional sequence analysis of Alu-SINEs and as molecular cladistic markers. The former approach resulted in placing *Tarsius* as a sister to the anthropoid primates (Zietkiewicz et al. 1999). The latter molecular cladistic SINE approach analyzed the presence and absence pattern of 118 loci with intronic Alu sequences (Schmitz et al. 2001). Initially from these three Alu, SINEs were determined to be present at orthologous sites in *Tarsius* and all anthropoids, to the exclusion of the strepsirhines and outgroup representatives. In the latter, unoccupied integration target sites were detected. Another integration of an unfused Alu monomer was later added to the list (Schmitz and Zischler 2004). This Alu monomer might have been created by a deletion or it can be speculated that a monomer that was retropositionally active before the primate divergence regained the capacity to spread through the genome. Both the analyses of presence/absence and of substitutional evolution are not comparable, the latter representing a multilocus approach, whereas the former pinpoints one orthologous region in the primate genomes. Further retropositional evidence for a close affiliation of anthropoids and *Tarsius* was also provided by Kuryshev et al. (2001).

Taken together, all these repeat analyses result in four strong molecular cladistic arguments in favor of a sister group relationship of tarsiers and
anthropoid primates. Since in more than 100 analyzed Alu-loci no inconsistency leading to contradictory interpretations could be detected, the likelihood of confounding these results by lineage sorting or reversals is exceedingly low. Thus, monolocus evidence as well as multilocus evidence from different SINEs (Zietkiewicz et al. 1999; Kuryshev et al. 2001) corroborates the monophyly of haplorhine primates (Anthropoidea and Tarsiiformes) from an entirely new molecular perspective (Figure 2.3).

Besides a scanty fossil record, the main problem that is encountered doing phylogenetic research on New World monkeys is due to the radiation-like evolution of extant platyrrhine diversity. The huge diversification in a short time span after the New World was colonized by the proto-platyrhines often results in long branches leading to closely spaced splitting events—a problem neither morphologists nor molecular biologists can adequately deal with without a great deal of data at hand.

Figure 2.3
Haplorhine phylogenetic affiliations displaying the sister group position of Tarsius to anthropoid primates—supported by four SINE insertions—and a broad taxonomic representation of platyrrhines (topology as in Goodman et al. 2005). Molecular cladistic arguments are summarized from Schmitz et al. (2001), Schmitz and Zischler (2004), Singer et al. (2003), and Ray et al. (2005). Taxa in gray were not tested in the SINE analysis
At least 16 New World monkey genera are recognized. Both the genus and species numbers fluctuate. Several scenarios for platyrrhine origins and transoceanic migration events have been noted. The most basic issue is that of a common New World monkey origin and the question of how the platyrrhine ancestors colonized their present geographic range. WGS data for one platyrrhine representative are about to be generated that will fuel the development of marker systems that can be subsequently used in comparative approaches to elucidate New World monkey phylogeny. Initially SINE data from three independent loci were presented that strongly point to a monophyletic origin of extant New World monkeys (Singer et al. 2003) corroborating SINE evidence in the major histocompatibility complex (Kriener et al. 2001) and other molecular data based on sequence comparisons. Recently, Ray et al. (2005) added an impressive list of 183 molecular cladistic Alu-SINE markers that were informative for platyrrhine evolution. The number of molecular cladistic markers pointing to a platyrrhine monophyly now approaches 100. Several molecular cladistic SINE arguments support a sister group relation of the Cebidae and Atelidae with the Pitheciidae branching off before the common ancestor of Cebidae and Atelidae. Together with the SINE information provided by Singer et al. (2003), three orthologous SINEs represent shared-derived character states for the Cebid clade including Aotus, Saimiri, Callithrix, and Saguinus. The amount of arguments basically rules out a confounding of the resulting interpretations by lineage sorting. A comparison of SINE-based evidence to conventional sequence analysis and fossil evidence is given in more detail by Ray et al. (2005).

Catarrhini, the cercopithecoid monkeys and hominoids, represent the youngest group of primates. Extant catarrhines can be partitioned in the Cercopithecoida (Cercopithecinae and Colobinae) and the hominoids, including the gibbons, orangutans, gorillas, chimpanzees, and bonobos. Salem et al. (2003) used altogether 133 Alu-SINEs to delineate the hominid phylogeny that is congruent with previous views obtained from all sorts of data. Gibbon phylogeny is difficult. A consensus is emerging that favors recognizing the four genera Nomascus, Symphalangus, Bupithecus, and Hylobates. Their phylogenetic affiliation is disputed, but the unavailability of material suitable for molecular analyses renders thorough taxonomic sampling near impossible. As to the marker site, gibbon WGS data are in the pipeline and are a likely source of numerous future marker systems.

A synthetic view of catarrhine evolution based on neontological—including molecular—and paleontological data is at hand (Stewart and Disotell 1998). Xing et al. (2005) performed a SINE analysis by cross-species checking the presence of altogether 297 Alu-SINEs (Figure 2.4). The formerly less disputed phylogenetic
relationships among the Papionini, a group of catarrhines consisting of the genera *Macaca*, *Papio*, *Theropithecus*, *Lophocebus*, and *Mandrillus*, and *Cercocebus* are well supported by several SINEs indicative for the respective branches. Moreover, the affiliations among the Cercopithecini (comprising *Cercopithecus*, *Chlorocebus*, *Erythrocebus*, *Allenopithecus*, and *Miopithecus*), formerly intensively disputed, are also now corroborated by a multitude of SINE arguments that rule out any confounding of the phylogenetic interpretations caused by lineage sorting. Finally the question of monophyly of Asian and African colobines has also been approached by SINE analyses. As in the case of the gibbons, however, the Asian and African colobines can be firmly assembled but the taxonomic representation is not complete, leaving out such taxa as *Piliocolobus* and *Simias*. Thus colobines are somehow representative for the whole primate divergence. Though markers are at hand and are likely to increase in the near future, mainly due to the WGS and ENCODE sequencing initiatives, there are still quite a few gaps remaining before we will get a complete view of the phylogenetic affiliations of all extant primate genera.
2.3 Future directions

The most striking phylogenetic problem in primate evolution is still that of the enigmatic primate origin and affiliation to other Euarchontoglires. Considerable improvement of this situation will be obtained by obtaining *Tupaia* WGS data. These will help to establish meaningful comparisons of rodents with *Tupaia* and primate genomes. Markers will be defined that need to be tested in dermopterans and that cover the complete scandentian divergence. It can be anticipated that this will lead to a well-supported phylogenetic framework linking eutherian model systems and humans.

Looking at the extant taxa, molecular processes shaping primate genomes can thus be pinpointed on the platform of a settled phylogenetic framework. Moreover, a phylogenetic framework linking extant primates and primate-related eutherians might be helpful in formulating hypotheses in which fossils are incorporated, thus yielding information on the morphological character evolution and phylogenetic affiliations of extant and extinct primate species.

Furthermore, total evidence approaches linking molecular and, e.g., morphological information need to be put forward. Experimental data as well as bioinformatic tools need to be improved in this context. Maximum parsimony has been the method of choice for combined molecular and morphological data sets, and this is above all a problem when analyzing deep splits with molecular data. New approaches include Bayesian methods, which allow molecular and morphological data to have their own evolutionary models.

More sequence data will enable us to more reliably estimate divergence and origin times—clearly mtDNA, with its peculiar mode of evolution, needs a backup in the form of sequence data of sufficient quality and quantity.

To delineate character evolution, a better coverage of all primate taxa including strepsirrhines and tarsiers and the non-primate taxa is of the outmost importance.

Finally, with more sequence data and a phylogenetic framework at hand, the functionally important molecular changes also involving SINEs will be the future research directions in primate genetics. Interspersed repeat sequences constitute additional important forces that possibly alter gene function and regulation (Samonte and Eichler 2002). Exaptations of repetitive elements, epigenetic and posttranscriptional modifications linked to SINEs, the role of SINEs in triggering large-scale genomic changes including segmental duplications and inversions, are just a few of the effects SINEs can exert on genomes and transcriptomes, thus potentially triggering major phenotypic changes. They show that in the future retroposon analyses will be worthwhile experimental approaches for both pattern and process analyses in primate evolutionary research.

3 Fossil Record of the Primates from the Paleocene to the Oligocene

D. Tab Rasmussen

Abstract

The early fossil record of primates is very rich, but it is limited to nonrandom windows in time and space based on vagueries of historical geology. Most primates known are fossil taxa and their value to studies of phylogenetics, paleoenvironments, and biogeography cannot be overstated. True primates demonstrating orbital convergence, reduced olfaction, relatively large brains, and grasping extremities are known from the earliest Eocene of North America, Europe, and Asia, suggesting a much older origin of the order. The Eocene was a primate golden age, with diverse radiations of adapoids, omomyoids, and anthropoids among others. The phylogenetic relationships of some groups remain uncertain, largely because they show mosaic patterns of features that do not conform to expectations derived from the few living primates. True strepsirhines are documented in the Eocene of Africa. Basal tarsiers are known from the Eocene of Asia. Undoubted early anthropoids appear in Africa by the Middle to Late Eocene. Proposals that Eocene Asian primates might be related to the African anthropoids remain hypothetical. By the Oligocene, anthropoids had diverged into catarrhines, platyrhines, and basal lineages now extinct. The apelike catarrhines that gave rise to monkeys, apes, and humans were present in Africa before the Oligocene–Miocene transition.

3.1 Introduction

We are lucky to have a very good fossil record of primate evolution in the Early Tertiary. Many dozens of genera are known, hundreds of species, and tens of thousands of individual specimens which in their geological contexts preserve useful information about morphology, time, and paleoenvironments (Fleagle 2000; Hartwig 2002). Of course, even with a rich fossil record, our paleontological view of primate evolution is still restricted to a relatively few number of geographic locations at any given point in time. This is because the geological processes that
generate substantial terrestrial sedimentary deposits in which primate remains may accumulate and be preserved are relatively rare, usually being associated with episodes of mountain building, aggrading coastal flood plains, deposition of large river deltas, sedimentation in rift valleys, or on a smaller scale, with local lake bed sediments, limestone cave breccias, and fissure fills. Most of the earth’s terrestrial surface is wearing away at any given time, not being buried. The primate fossil record is one of great richness in terms of overall number and quality of fossil specimens, but at the same time it is significantly limited to a relatively few, nonrandom windows in space and time.

The purpose of this chapter is to review the current fossil record of primates from the Paleocene, Eocene, and Oligocene with a special emphasis on its relationship to key phylogenetic issues in paleoanthropology. The phylogenetic value of the fossil record can hardly be overstated. Any given fossil taxon is represented by only a few anatomical systems—usually some teeth, and if lucky, entire dentitions, cranial remains, or postcranial skeletal elements—which pales in comparison to the complete anatomical, behavioral, and genetic data available on living primates. Conversely, the living primate record is limited to a relatively few taxa, a very small sample of all primates that have ever existed. Entire radiations of phylogenetically important groups are missing from the extant record (like three-premolar Old World anthropoids). And worst of all, the living primate record is restricted to an incredibly narrow slice of time—the present—which is no more important in primate evolutionary history than is any other equally thin slice of time from the past. Far more fossil primates are now known than living species, and the number of fossil taxa will continue to increase. Fossil primates show unique character combinations that would never have been inferred from living species, they provide information on evolutionary sequences, and they help tease apart problems of evolutionary convergence and parallelism. In this age in which DNA analyses are justifiably emphasized as a pivotal research tool, it is important to note that only a small minority of primate lineages will ever be known by their DNA. To incorporate genetic analyses into a broader, cohesive view of primate evolution, we will always be dependent on morphological analyses of fossils that allow us to extrapolate the genetic interpretations into the rich temporal and ecological framework of the fossil record.

The taxonomic scope of this chapter will be restricted to euprimates, those taxa that belong in a clade defined by grasping hands and feet, orbital convergence and a postorbital bar, and a petrosal auditory bulla. As Chapter 1 of this volume explored, there existed complex radiations of Paleocene and Early Eocene plesiadapiform mammals that may or may not be allied with euprimates. The recent discovery of primate grasping in the non-euprimate *Carpolesus*, which lacks orbital convergence, highlights how important the fossil record of plesiadapiforms and their allies will be untangling phylogenetic and adaptive questions about the
origins of primates (Bloch and Boyer 2002). In this chapter, I will devote most of my attention to undoubted euprimates that illuminate the basal divergence of the three major living clades—Strepsirhini, Tarsiiformes, and Anthropoidea.

### 3.2 The earliest euprimates

Mammalian taxa that are routinely considered in discussions of the geologically earliest euprimate include the following taxa: *Altiatlasius, Altanius, Donrusselia, Teilhardina*, and *Cantius*. *Altiatlasius* appears in the Paleocene of Africa, the other four appear nearly simultaneously at the base of the Eocene in the Northern Hemisphere, with representatives of one or more of these taxa present in Asia, Europe, and North America (Rose 1995; Covert 2002).

#### 3.2.1 *Altiatlasius*

*Altiatlasius* is known from a handful of isolated upper and lower teeth recovered from the Paleocene of Morocco (Sigé et al. 1990). The teeth were recovered from a small deposit consisting of clasts and mammal teeth of apparent terrestrial origin transported into estuarine sediment where they came to rest. This tiny glimpse of terrestrial micromammal fauna is our only significant view into the Paleocene of Africa. The lower molars have high, complete trigonids, and low talonids which are slightly broader than those found in many insectivores. Tooth position of the isolated specimens was interpreted in a reasonable way and yields a very primate-like dental pattern. If the interpretation of these remains is correct, then *Altiatlasius* would be the earliest euprimate known and would have several important implications to primate evolution. It would suggest that euprimates originated in Africa and they spread northwards into Asia, Europe, and Africa as the global-warming event of the Paleocene–Eocene boundary sent tropical rainforests expanding into the higher latitudes.

The problem with *Altiatlasius* is that its primate-like teeth mirror, in a general sense, the primate-like teeth long known from the Paleocene of the northern hemisphere, which have caused so much phylogenetic uncertainty, such as those of the plesiadapiforms and other dentally primate-like groups (such as apatemyids). If the Paleocene of the northern continents was full of groups that could be characterized as “dentally primate,” then we must consider the possibility that such groups occurred in Africa, as well. Unfortunately, it seems unlikely that substantial deposits of Paleocene age will be forthcoming from other parts of Africa any time soon. The discovery of any such geological contexts will be of great value and should be considered a paleoprimatological priority.
3.2.2 Altanius

This interesting mammal is from the Early Eocene of Mongolia (Rose and Krause 1984; Gingerich et al. 1991). It is known from several jaws preserving teeth and shows a generally primate-like dentition. The interesting debate that emerged soon after the description of Altanius was whether this genus was a euprimate or a carpolestid (a question that preceded the new discoveries about the limbs and cranium of Carpolestes; Chapter 1). The most distinctive feature of the lower dentition of Altanius was that it had a distinctly high, buccolingually compressed trigonid on the first molar and a high, relatively complex fourth premolar, which seemed to hint at the unique dental specializations of carpolestids. While new finds of better material, including upper jaws, seemed to resolve the debate in favor of euprimate affinities, the new anatomical knowledge linking North American Carpolestes to euprimates and the discovery of structurally primitive but geologically late carpolestids in eastern Asia makes Altanius of some interest in terms of testing ideas about a basal carpolestid-euprimate radiation.

3.2.3 Cantius

This is the earliest euprimate genus known from the triad of grasping extremities, orbital convergence with a postorbital bar, and a petrosal bulla. Thousands of fossils of this genus have been recovered that represent several species from the earliest Eocene of North America and Europe. While the geologically oldest species, C. torresi of Wyoming, is known only from dental remains (Gingerich 1986), somewhat later (but still Early Eocene) species of the genus include partial crania and limb skeletons that are indisputably euprimate (Dagosto 1993). The very dense, continuous stratigraphic sequences preserved in the Bighorn Basin, Wyoming, allow for confident extrapolation of evolving lineages of Cantius, illuminating an evolutionary pattern that involved the acquisition of larger body size, upper molar hypocones, and mesostyles. The earliest associated skeletal remains of Cantius suggest a Lepilemur-like vertical clinger and leaper, but one that was probably diurnal in activity pattern, with teeth and body size suggesting frugivory-insectivory (Rose and Walker 1985).

3.2.4 Teilhardina

This genus is found alongside Cantius in the Bighorn Basin of North America, as well as in the earliest Eocene of Europe and Asia. Recently, a cranium of the genus has been described from Asia; this represents the oldest euprimate cranium in the
fossil record, complete with postorbital bar, a moderate level of orbital convergence, a small rostrum by Eocene standards, and a relatively large braincase (Ni et al. 2004). *Teilhardina* is a small primate with sharp, perforating teeth that indicate insectivory, while the molars also have the characteristic broad talonid of euprimates (distinguishing them from insectivores) that probably reflects a significant reliance on fruit or other grindable plant foods.

The Asian species of the genus is *T. asiatica*, the European species is *T. belgica*, and North America’s earliest species is *T. brandti*, followed later in time by the better known *T. americana*. The North American species are linked very reliably, via a dense stratigraphic record, to a diverse radiation of other small-bodied North American euprimates known from crania and postcrania. Those will be discussed later.

### 3.2.5 Other primitive early euprimates

Another primate genus that occurs in the earliest Eocene of Europe is *Donrussellia*, a tiny adapoid from Belgium. Its phylogenetic relationships to other Eocene primates are not as well worked out as those of *Cantius* and *Teilhardina*, but it does seem to be related to an important radiation of European adapoids.

“Geologically oldest” does not mean “most primitive,” of course, and comparative anatomical studies have suggested that a North American genus, *Steinius*, which is of Early Eocene age, may be more primitive structurally than its earlier relatives *Teilhardina* and *Cantius* (Rose 1995). It is important to note that the dentitions of all three of these North American genera are very similar to each other, more so than any of them is to modern tarsiers, strepsirhines, or most other later groups of primates. This suggests that no matter which later primate groups we may tie these Early Eocene forms to phylogenetically, we are probably sampling near the base of a radiation of primates that moved north with the wave of advancing tropical conditions that mark the Paleocene–Eocene transition (Clyde and Gingerich 1998).

### 3.3 The basal divergence of extant primate clades

An important phylogenetic question is how these few known euprimates of the earliest Eocene and their close kin in younger Eocene deposits are related to the three major extant primate clades. The evergrowing body of genetic data seems to be converging toward a consensus that the split between today’s three major euprimate groups—Strepsirhini, Tarsiiformes, and Anthropoidea—occurred
within a very short temporal interval before a euprimate fossil record is available (Yoder et al. 1996; Yoder 2003). The term “strepsirhine” is used here in the strict sense of the clade containing today’s tooth-combed prosimians, not in the paraphyletic sense that may converge on the term “prosimian” (Rasmussen and Nekaris 1998). This basal three-way divergence may prove to be an unresolvable or difficult-to-resolve trichotomy analogous in ways to the debates several years ago about the human-chimp-gorilla clade. Most analyses involving time estimates—whether by molecular clock or other means—now suggest that the deep three-way split occurred before the beginning of the Eocene. Age estimates range from as young as the Paleocene to quite a bit older (Tavare et al. 2002).

If a pre-Eocene date is correct, then representatives of a strepsirhine lineage, a tarsier lineage, and an anthropoid lineage would be expected in the Early Eocene, were we lucky enough to sample the right geographic regions. It is also important to note that there may be other basal primate lineages, outgroups to the three extant clades or embedded within the trichotomous branching. The three extant clades are important to us because they survived to the present, not necessarily because they dominated evolutionary or ecological dynamics in the Early Tertiary.

Most work on primate phylogeny starts with a basic euprimate dichotomy into haplorhines and strepsirhines. The dichotomy may be correct or not, given the problems of interpreting the three-way split (Yoder 2003). But the fact that the correct answer about the trichotomy is currently unknown and that we have not seen toothcombs and cannot see placentas in the earliest euprimate fossil record suggests that this dichotomy should not serve as an empirical starting point. Fossil evidence should help tell us whether these taxa are useful; theoretical perceptions about suborders should not dictate our interpretation of fossils. There are so many problems with the application of “Haplorhini” to the fossil record (Rasmussen 1994) that it would be preferable (but admittedly still problematic) to start looking at local primate radiations—well defined morphologically, temporally, and geographically—and work our way up from there to major subordinal divisions. Some early euprimates may resist being affined confidently with strepsirhines, tarsiiformes, or anthropoids, due to a lack of sound, multi-character, and stratigraphically buttressed fossil evidence.

To clarify the nomenclature used here: none of the three main euprimate divisions—Tarsiiformes, Strepsirhini, or Anthropoidea—is used in a paraphyletic sense. A primate that cannot be attributed confidently to “Haplorhini” does not automatically become a strepsirhine. In this chapter, primates can hold “prosimian” status, meaning we do not know to which of the three extant branches it is closest.
3.4 The Adapidea

Phylogenetic analyses of Early Eocene primates have traditionally tied *Cantius* and *Donrussellia* into a series of very important and geographically distinct radiations of a single family Adapidae, or as more commonly construed in recent years, into a cluster of families classified together as adapoids or adapiforms (Franzen 1987). These adapoids are generally characterized as arboreal quadrupeds and leapers, with diverse diets including species specialized toward frugivory and folivory, and body sizes ranging from those of mouse lemurs to howler monkeys (Gebo 2002). They have vertical, spatulate incisors, often with fused mandibular symphyses, and in some cases, at least, sexual dimorphism in canine and body size. The cranium is characterized by relatively heavy faces with small cranial capacity, simple postorbital bars, and petrosal bullae with free ectotympanic rings like those of extant lemurs. The carotid circulation is variable, most notably with some species having large promontory canals and others lacking these.

The adapoids have often been characterized as “lemur-like,” but the extent to which this reflects primitive primate similarities or actual phylogenetic ties remains unresolved. Authors of the last few decades have not been able to make a sound case for an actual adapoid-lemuroid clade, although adapids are often classified as strepsirhines or prosimians in a paraphyletic sense. In sharp contrast, a number of researchers over the years have concluded that a small handful of derived specializations shared by adapoids and anthropoids suggest that adapoids are the prosimian-grade ancestral stock of anthropoids (see review by Miller et al. 2005). This phylogenetic notion was developed in a time before the discovery of very primitive, Eocene anthropoids in North Africa. The possible synapomorphies presented in support of this hypothesis include spatulate incisors, lacrimal foramen positioned inside the orbit, presence of a large zygomaticofacial foramen, mesial canine groove, sexual dimorphism in canine and body size, and fused mandibular symphyses.

3.4.1 Notharctines

In North America, *Cantius*, or a form similar to it, gave rise to a major radiation of diurnal, herbivorous, arboreal primates that includes some of the best-known fossil primates. This group can be classified as the subfamily Notharctinae, now usually placed within a family Notharctidae (which in most taxonomic schemes also includes Cercamoniinae). Notharctines are common components of the tropical faunas found in the Early Eocene of the Rocky Mountains.
(Wasatchian and Bridgerian Land Mammal Ages), but they are extinct in that region by the Middle Eocene (Uintan). The Rocky Mountain taxa include *Cantius, Pelycodus, Copelemur, Smilodectes*, and *Notharctus* (Figure 3.1). In the lower latitudes of southern California (which lay even more southerly during the Eocene), notharctines persisted into the Uintan (represented by one genus, *Hesperolemur*) (Gunnell 1995). *Smilodectes* and *Notharctus*, which are known from crania and nearly complete limb skeletons, were large species (lemur or monkey-sized) characterized by folivory, leaping adaptations, and sexual dimorphism. They have been reconstructed as arboreal, gregarious primates similar adaptively to certain of the larger-bodied extant strepsirhines such as lemurids and indrids.

The notharctines became extinct at the end of the Bridgerian Land Mammal Age in the Rocky Mountain region, probably in association with a gradual loss of rainforest and closed woodland habitats (Townsend 2004) and, by inference, a slide toward cooler, drier climatic conditions. They left no descendants in North America but have been linked with the Late Eocene Asian radiation of amphipithecines (Ciochon et al. 2001).

### 3.4.2 Cercamoniines

In Europe, early *Cantius* or a form like it gave rise to a tremendous Eocene radiation of primates often classified together in the subfamily Cercamoniinae.
(Gingerich 1977a; Franzen 1987, 1994; Godinot 1998). Interestingly, the cercamonine derivates of primitive *Cantius* developed a hypocone from the cingulum (as do most primates, including anthropoids) but unlike the evolutionary derivation seen in notharctines in which the hypocone gradually splits away from the protocone. The cercamoniines represent one of the most diverse primate radiations documented in the fossil record, but most taxa are individually poorly known and understudied. Body sizes ranged from taxa smaller than a mouse lemur (*Donrussellia* and *Anchomomys*) to monkey-sized (4000 g) heavy-duty frugivores with deep jaws and flat, grinding molars (*Cercamonius*). They include primates interpreted as insectivores, frugivores, and folivores. Postcranial diversity is poorly documented, but they include at least a variety of arboreal quadrupedal and leaping forms (Thalmann et al. 1989; Franzen 1994).

Geographically cercamoniines are most diverse in Europe, but remarkably, and in contrast to most other Eocene radiations, they are also known from North America, Africa, and Asia. The lone North American genus is *Mahgarita*, known from the Late Eocene of Texas, which closely resembles the European genus *Europolemur* (Figure 3.2). The cranial remains of *Mahgarita* have been the subject of analyses regarding the possible phylogenetic relationships of adapoids to either strepsirhines or anthropoids (Rasmussen 1990). The African cercamoniine taxa include *Aframomius*, surprisingly similar in dental details to both *Europolemur* and *Mahgarita* (Simons et al. 1995; Figure 3.3) along with a variety of smaller, *Anchomomys*-like forms, discussed below. The Asian cercamoniine is known from a few dental remains of Middle Eocene age (Beard et al. 1994). Cercamoniines range in age from Early Eocene to Early Oligocene, a record of *Anchomomys* being the sole primate survivor of the Grand Coupure in Europe. Cercamoniinae is a diverse, widespread Eocene clade which demands further study. Extrapolations about cercamoniine paleobiology and phylogeny derived from the better-known notharctines and adapines may be off base. Phylogenetic discussions about an adapoid derivation of Anthropoidea have more often centered around cercamoniines than any other group.

Vertebrate fossil remains from the Middle Eocene site of Messel, Germany, are among the most spectacular ever found from the Early Tertiary (Franzen 1994). Whole or partial skeletons were washed into a toxic lake that prohibited bacterial decomposition or scavenging by lake-living vertebrates. The result is beautiful, pressed remains of vertebrates, including a few of primates. One of these preserves the stomach contents of a cercamoniine, the first ever reported for an Early Tertiary primate (Franzen and Wilde 2003). The primate had been eating seeds and fruit.
3.4.3 Adapines

This group of European adapoids includes *Adapis* and *Leptadapis* which, along with the notharctines, are among the best-known adapoids. They appear in the Late Eocene Paris Basin of Europe, after most cercamoniines lineages have disappeared. The earliest record of an adapine is from the Middle Eocene of Asia (Beard et al. 1994), and it now seems likely that they are a group that spread into Europe late, after an origin in the Far East. *Adapis parisiensis*, an animal about the size of a slow loris (*Nycticebus*), shows skeletal features indicating a
Figure 3.3
Mandibles of *Aframonius diedes*, a cercamoniine adapoid from the Late Eocene of North Africa. This is the largest primate known from the diverse community of quarry L-41, Fayum, Egypt; other primate taxa preserved at that quarry include mouse-lemur-sized prosimians (*Anchomomys, Wadilemur*), a possible aberrant strepsirhine (loris-sized *Plesio Pithecus*), several callitrichine-sized three-molared anthropoids (*Proteopithecus, Arsinoea, Serapia, Qatrania*), and a two-premolared catarrhine (*Catopithecus*). This higher-level taxonomic diversity hints at Africa’s important role in early primate diversification, although a shortage of productive Eocene localities on that continent stymies efforts to understand the primate radiation there. (From Simons et al. 1994; illustration by B. Miljour)
quadrupedal and slow-climbing mode of locomotion, and its teeth suggest specialized folivory. *Leptadapis* was a larger animal (the size of a howler monkey, *Alouatta*), also folivorous, with a more generalized, quadrupedal limb skeleton (Dagosto 1983). Both taxa show sexual dimorphism (Gingerich 1981). Phylogenetically, adapines seem not to have given rise to any later groups, although a specific tie to strepsirhines has been considered at times (Gingerich 1975).

### 3.4.4 Amphipithecines

For many years, a few poorly preserved teeth and jaws of enigmatic primates known as *Amphipithecus* and *Pondaungia* were known from the Middle to Late Eocene of southern Asia, with uncertainty being expressed over whether these were adapoids or anthropoids (Ciochon and Gunnell 2002). In recent years, intense research interest in a possible Asian origin of anthropoids has spurred significant new collecting efforts that have yielded an important new sample of material belonging to these two genera and newly described relatives (*Siamopithecus*, *Myanmarpithecus*) (Ducrocq 1998; Takai et al. 2001). The new remains of cranial fragments and postcranial limb elements seem to establish solidly that the amphipithecines are very adapoid-like (Ciochon et al. 2001; Gunnell et al. 2002). Certain postcranial and dental features, including the presence of a pseudohypocone and mesiodistal compression of the paraconid and metaconid, are distinct similarities to notharctines, although the two clades show plenty of differences as well. The paleobiology of the amphipithecines, putting aside controversial phylogenetic issues, has been expertly evaluated (Kay et al. 2004).

Ironically, the anatomical features that initially generated interest in amphipithecines as possibly being anthropoids—heavy, deep jaws with broad, low-crowned, thick-enamed molars—have in the last 20 years been disproven as characters of basal anthropoids. Amphipithecines have persisted as candidates for anthropoid ancestry because they do resemble later Oligocene anthropoids from Africa, and also because of the attention directed to a very different group of small-bodied, insectivorous primates that co-occur with amphipithecines in Asia, the eosimiids (see below). At this point, a specific cladistic tie between amphipithecines and anthropoids seems remote unless they are both part of a broader adapoid–anthropoid radiation (which is a distinctly minority view). Apart from their geographic address, there are essentially no characters that meaningfully link amphipithecines and eosimiids to each other, which would seem to be the critical phylogenetic question at hand in assessing the only two known Asian groups of a hypothetical basal radiation of cladistic anthropoids.
3.4.5 Sivaladapines

In southern Asia, adapoids survived the global-cooling event marking the Eocene–Oligocene transition, which spelled extinction for most northern continent primates. Adapoids crop up in outcrops of Late Miocene age in India and Pakistan, and it is a shame that we only missed them by a few million years because their DNA and soft tissue structures might well have earned them status as phylogenetic enigmas equal to tarsiers. As it is, we have jaws and teeth of large-bodied (up to 4 kg in mass), highly folivorous adapoids that moved through tropical rainforests and woodland alongside apes, monkeys, and lorisines (Gingerich and Sahni 1979, 1984) (Figure 3.4). The earliest representatives of this group appear in the Eocene of China, in the form of Hoanghonius and a few other taxa (Qi and Beard 1998; Tong et al. 1999). It seems that adapines, cercamoniines, and sivaladapines were present in Asia during the Early to Middle Eocene, and if amphipithecines can be added to the adapoid radiation there, then clearly Asia was the center of higher level adapoid diversity.

3.5 Omomyoidea

Unlike the phylogenetic ambiguity surrounding adapoids, the phylogenetic position of omomyoids seems to be indisputably tarsiiform (Gunnell and Rose 2002). While not matching modern Tarsius in the extreme expression of some of its bizarre-specialized features, omomyoids do trend toward distinctly tarsiiform morphology in most cases. For example, one of the better-known taxa—Late Eocene Necrolemur of the Paris Basin—shares with tarsiers styliform incisors, guttered glenoid fossae for the temporomandibular joint, a tubular ectotympanic, the presence of a suprameatal foramen, greatly elongated navicular and calcaneus, and a fibula fused to the tibia (Rosenberger 1985). Putative synapomorphies show up in the teeth and masticatory system, the basicranium, and the locomotor skeleton, providing support for the idea that these are not isolated cases of convergence. It could be argued that the styliform anterior dentition is primitive for primates, in which case the spatulate incisors of adapoids become possible synapomorphies linking them with anthropoids (Gingerich 1977b; Rasmussen et al. 1995; Rose 1995).

One of the key corollaries of the hypothesized phylogenetic tie between Early Tertiary omomyoids and Tarsius is that the partial postorbital closure of Tarsius must have been derived independently from the postorbital plate of anthropoids because it is absent from Eocene forms. This is one of two primary lines of evidence to suggest that the proposed synapomorphy of Tarsius and
anthropoid orbits is incorrect (the other being that the *Tarsius* plates are formed of expansions of the maxilla and sphenoid, while the anthropoid plate is primarily zygomatic; Simons and Rasmussen 1989). This case is a good example of how morphological evidence preserved among the much more diverse primates of the past, which show novel character combinations, may have a critical bearing, perhaps a definitive one, on resolving controversial phylogenetic problems.

Figure 3.4
Maxilla with P3-M3 and mandible with an almost complete lower dentition of *Sivaladapis nagrii*, a monkey-sized folivorous adapoid from the Late Miocene of Asia. By this time, most Eocene adapoids and omomyoids had long been extinct, but the sivaladapines continued to thrive as part of a primate fauna that also included hominoids, cercopithecoids, and lorisines. (From Gingerich and Sahni 1984; illustration by B. Miljour)
3.5.1 Anaptomorphines

In North America, primates similar to Early Eocene *Teilhardina* gave rise to a diverse radiation of small-bodied, leaping, primarily insectivorous primates. Studies of these fossil anaptomorphines in a stratigraphic context have been very important in understanding tempo and mode in evolution and made important contributions to the punctuated equilibria debates of a quarter century ago (Rose and Bown 1984; Bown and Rose 1987). These are the kinds of phylogenetic studies that actually relate to important evolutionary issues rather than to nomenclatural tiffs. Anaptomorphine crania are known for *Teilhardina*, *Tetonius*, and *Shoshonius*. The cranium of *Tetonius* was found in the nineteenth century and has been important in shaping historical views of primate phylogeny (Figure 3.5). *Tetonius* and *Shoshonius* have each been interpreted as being

![Figure 3.5](image)

Figure 3.5
Cranium of the Early Eocene North America anaptomorphine *Tetonius* in side view (left) and the Late Eocene European microchoerine *Necrolemur* in front view (right). These two taxa were historically important in demonstrating that uniquely tarsiiform features were present in Eocene omomyid primates. The presence of tarsiiform omomyids in the earliest Eocene is consistent with molecular data suggesting the divergence of the three major extant lineages—tarsiiforms, strepsirhines, and anthropoids—occurred more than 55 Ma

within the tarsiiform clade and, therefore, outside any potential ancestry of Anthropoidea (Beard et al. 1991). Anaptomorphines were a common and diverse component of Early Tertiary communities in North America. The last surviving member of the group was *Trogolemur*, which appears as late as the Middle Eocene, after notharctines have disappeared from the Rocky Mountain region.
3.5.2 Omomyines

Ecologically, the omomyines were to North American tropical communities what the cercamoniine adapoids were in Europe—an ecomorphologically diverse radiation of primates that spanned the dietary spectrum from insectivores to frugivores and folivores, and the body mass spectrum from animals less than 200 g to some the size of lemurs (>2500 g). Also like the cercamoniines, omomyines have a broad geographic distribution; *Asiomomys* and *Macrotarsius* are found in the Middle Eocene of China (Beard et al. 1994). Omomyines probably originated from an anaptomorphine-like primate, perhaps something like *Steinius*. The radiation peaked during Bridger times (Gunnell and Rose 2002; Muldoon and Gunnell 2002). Among the best-known species is *Omomys carteri*, which is represented by hundreds of dental specimens, and an impressive collection of postcranial remains recovered from a single paleosol in the Bridger Basin (Anemone and Covert 2000). *Omomys* was a small, insectivore–frugivore with an arboreal quadrupedal locomotor pattern capable of leaping; it is interpreted as being more of a generalized, cheirogaleid-like primate than extremely tarsier-like. Another omomyine, *Hemiacodon*, also lacks some tarsier specializations such as fused tibia–fibula, although the navicular is elongated compared to those of anthropoids and strepsirhines (Dagosto 1993).

Upon the extinction of notharctines in the North American interior, several omomyines evolved large size (comparable to modern lemurs) and teeth that indicate frugivory and folivory (*Ourayia, Rooneyia, Macrotarsius*). The hindlimb skeleton of *Ourayia* indicates it retained from its omomyine ancestors certain leaping adaptations that seem to be more specialized than what is seen in cheirogaleids (Dunn et al. in press). The cranium of a Late Eocene form, *Rooneyia*, has enigmatically defied unambiguous placement in known clades. Unlike the cranium of *Necrolemur*, it is neither particularly tarsier-like nor does it resemble in any significant detail-specific features of strepsirhines or anthropoids. *Rooneyia* is probably the most important taxon to challenge the idea that all omomyoids are components of a monophyletic Tarsiiformes.

3.5.3 Microchoerines

The Late Eocene of Europe is characterized by three microchoerine genera: the small *Pseudoloris*, which resembles tarsiers in dental structure; the large *Microchoerus*, which has more cuspate teeth suggesting frugivory; and the medium-sized *Necrolemur*, the one taxon known from crania and some limb elements, which looks convincingly tarsier-like in several anatomical systems (Section 3.5;
A geologically older omomyoid named *Nannopithecus* from the Middle Eocene of Europe may be a connecting phylogenetic link between Early Eocene *Teilhardina* and the Late Eocene microchoerines; dentally it resembles anaptomorphines in many primitive respects.

### 3.6 Eosimiidae and Tarsiidae

Several jaws, teeth, and possibly referrable tarsal bones from the Middle Eocene of China have been argued to be basal anthropoids. The taxa include *Eosimias* and *Phenacopithecus* (Beard and Wang 2004). From the Late Eocene of Myanmar (alongside those enigmatic amphipithecines) comes a larger form called *Bahinia* (Gebo et al. 2002). All three taxa are placed in the family Eosimiidae, which is proposed to be the sister taxon of Anthropoidea (Beard et al. 1994, 1996; Beard 2002).

#### 3.6.1 Dental data and tarsier theory

The original dentally based hypothesis that *Eosimias* is related to anthropoid ancestry relied on proposed synapomorphies that were not particularly compelling, traits like premolar exaenodonty (i.e., buccally bulging crowns) and a 2-1-3-3 lower dental formula, which can be found in other primate groups (Beard et al. 1994; Gunnell and Miller 2001). Given the historical record showing that bold phylogenetic hypotheses born of incomplete dental evidence often turn bad (*Ramapithecus* springs to mind), why has the eosimiid-as-anthropoid hypothesis garnered so much attention? Because it is generated from the very compelling theory that anthropoids must have been derived from a tarsier-like ancestor (Kay et al. 1997; Ross et al. 1998).

The history of this idea is central to the last century of paleoprimatology (Rasmussen 1994). In the 1890s, a Dutch anatomist named Hubrecht published work suggesting that tarsiers were more closely related to anthropoids than either group was to strepsirhines based on placental structure. Later, Pocock gave the phylogenetic hypothesis a name in the Linnean hierarchy: Haplorhini. Pocock’s work was based on the comparative anatomical study of soft tissues of the nose and the retina. British anthropologists were so taken by tarsiers that the prominent scholar Frederich Wood Jones went so far as to propose that *Homo* evolved from tarsiers, not from apes. In the mid-century, paleontologists were comfortable recognizing a clade formed of tarsiers and anthropoids among living taxa, but they also were confident about an omomyid-tarsier clade nested within
that one. That idea was challenged in the 1970s by the proposal that tarsiers and anthropoids shared a common ancestor not just among the living taxa but also relative to all known fossil taxa at the time. The hypothesis has been called the “strict tarsier-anthropoid clade.” This cleaved tarsiers off Necrolemur and other Eocene tarsiiforms and attached them tightly to Anthropoidea, based on postorbital closure and middle ear configurations of carotid circulation and septum development that were not present in those otherwise seemingly tarsiiform Eocene primates. The apparent soft tissue and genetic similarities between tarsiers and anthropoids were entirely irrelevant to testing the strict tarsier-anthropoid clade because fossil omomyoids (or adapoids or any other group) could not be tested for those traits. The strict hypothesis was a uniquely skeletal hypothesis that was clearly intended to separate anthropoids and tarsiers from the Eocene radiations of omomyoids, which for all practical purposes have no noses, placentas, or DNA.

This century-long tradition projects an unambiguous phylogenetic prediction: the earliest anthropoids evolved from a tarsier-like primate that was not too tarsier-like (too specialized) to give rise to anthropoids (i.e., no long foot bones, no guttered temporomandibular joint, no styliform incisors, no fused tibiofibula, etc.). Eosimias is compelling because it is a very tarsier-like primate that is not known to have anatomical specializations excluding it from anthropoid ancestry. This is not to say that Eosimias is generalized enough to give rise to anthropoids; at this point, it merely means that we do not know whether that is the case or not, based on lack of the most salient cranial and postcranial traits. The eosimiid hypothesis of anthropoid origins will succeed or not based on future fossil finds of more complete skeletal remains.

On the basis of the available dental material of eosimiids, which includes complete lower dentitions, and a fair number of upper teeth, it appears that they are very tarsier-like animals. Similarities in the lower dentitions of Eosimias, Tarsius, and an African Oligocene primate named Afrotarsius are pervasive (Simons 2003). In the molars, these genera differ from each other mainly in the angle of the paracristid. Eosimias differs from Tarsius in that the former retains the primitive two pairs of primate incisors, while Tarsius has only one pair. In both cases, the incisors are small, fairly vertical in placement, and pointed at the apex. On this evidence, Eosimias would seem to be a good candidate as two-incisored tarsiid.

Other teeth from China have been described as members of the modern family Tarsiidae (Tarsius eocaenus, Xanthorhysis tabrumi). Paralleling these finds, a primate lower jaw and teeth that closely resembled living Tarsius was recovered from Early Oligocene sediments in the Fayum, Egypt; this was identified as a tarsiid and named Afrotarsius (Simons and Bown 1985). Later, when eosimiids
were discovered, *Afrotarsius* and *Eosimias* were quickly reclassified into a single family, which supposedly consisted of basal anthropoids (Kay et al. 1997). When a fused primate tibia and fibula consistent in size with what would be expected of *Afrotarsius* was found in the same Fayum quarry that yielded *Afrotarsius*, a quarry with no other known mammal that could accommodate such a bone, it was suggested that therefore eosimiids were tarsiid after all (Rasmussen et al. 1998). Proponents of the eosimiids-as-anthropoids idea merely dropped *Afrotarsius* from their clade, now ignoring the evidence they had used to affix it there in the first place, which is exactly the same kind of evidence that supported the *Eosimias*-anthropoid clade to begin with.

### 3.6.2 The tiny foot bones of China

From the same fissure-fill deposits that have yielded dental remains of *Eosimias*, tarsiids, cercamoniines, adapines, omomyines, and a range of non-primate mammals (Beard et al. 1994) come small isolated tarsal bones that have been interpreted as those of haplorhine primates (Gebo et al. 2000a, b). Some of these bones would represent the smallest primates ever known. Quite a few tarsals and teeth are known, and deciding on associations seems to be difficult, given the diversity of dental taxa. These bones clearly have great promise in understanding primate phylogeny and paleobiology, but at present, drawing confident inferences from them is as problematic as drawing inferences from isolated teeth. The supposed haplorhine features require confirmation by quantitative comparisons among Eocene primates, and the dental associations must be established. While these primates offer great promise, it is fair to say that there is still no confidently reconstructed taxon of Chinese fissure-fill primates.

### 3.7 True anthropoids

One of the most exciting developments in paleoanthropology in the last two decades has been the total transformation of our views regarding early anthropoids (Dagosto 2002). The traditional and widely accepted theoretical views about the adaptive origin of anthropoids centered around the globally widespread cooling and drying that occurred at the Eocene–Oligocene transition (Cachel 1979). As theory had it, the change in climate required the evolution of larger body size and a reliance on tougher, more resistant food items, which in turn required heavier jaws, robust bunodont molars, and fusion of the mandible and frontal bone. Under this adaptive perspective, it did not really matter at the taxonomic level whether early anthropoids were derived from Eocene tarsiiform primates,
or from more generalized and primitive adapoids. The scenario about an ecological switch held sway, regardless of the phylogenetic origin.

With the discovery of Eocene anthropoids in Egypt, Oman, and Algeria, all components of this picture changed (Kappelman et al. 1992; Godinot 1994; Simons and Rasmussen 1995; Thomas et al. 1999). These new anthropoids have modern-type postorbital closure but no mandibular fusion (Simons 1990; Simons and Rasmussen 1996). The body masses of these early anthropoids are tiny, the size of marmosets. The teeth are of prosimian grade, with three intact trigonid cusps raised well above the talonid basin. Hypocones are often small and weak. The anthropoids occur in paleoenvironments that show no evidence of a switch to cooler, drier conditions (Rasmussen et al. 1992). Indeed, basal anthropoids lived alongside cercamoniine adapids that are closely allied with those of the European Eocene. No dramatic ecomorphological shift is evident. Eocene anthropoids were small, insect- and fruit-eating primates with quadrupedal arboreal locomotion, differing from other Eocene primates by inexplicably having complete postorbital closure (see adaptive proposals on this by Ross 1996, 2000). It now appears possible that the earliest anthropoids represent an ancient radiation of primates in Africa independent of the adapoid-omomyoid-tarsioid radiations known by fossil evidence from the northern continents (Miller et al. 2005). Most recently, dental and maxillary remains of putative anthropoids as old as the Middle Eocene have been found in the lowest strata of the Fayum, Egypt (Seiffert et al. 2005a). One of these new primates shows evidence of greatly enlarged, nocturnal orbits in combination with teeth decidedly unlike those of tarsioids, which promises interesting new debates about anthropoid origins in the coming years.

Postorbital closure in Eocene anthropoids is, to date, documented only in two genera, *Catopithecus* and *Proteopithecus*, both from a single, important quarry in Late Eocene levels of the Fayum, Egypt. By extension, similar postorbital closure is inferred for a variety of small-bodied primates known only by teeth and jaws. I use the term “basal anthropoid” for primates with postorbital closure but of uncertain cladistic relationship to the platyrrhine–catarrhine divergence. I do not include the various, controversial, open-socketed groups that are hypothesized to be sister taxa of the closed-socket clade (cf. Beard 2002).

### 3.7.1 Basal anthropoids

*Proteopithecus sylviae* is known by a complete cranium, several jaws with teeth, and some limb bones (Miller and Simons 1997; Simons 1997; Simons and Seiffert 1999; Seiffert et al. 2000). It occurs at quarry L-41 of the Jebel Qatrani Formation.
which, along with the Messel, is one of the most remarkable vertebrate quarries of the Early Tertiary. An astonishing density of mammal, bird, reptile, and fish remains is preserved there, in a very fine-grained sediment that was deposited with minimal depositional energy (as indicated by the intact marmoset-sized crania and fragile bird bones). Unfortunately, postdepositional processes crushed the bones nearly flat in most cases, although the teeth retain their three-dimensional shape. Unlike the Messel lake beds, where articulated skeletal associations are often found, the material from quarry L-41 is disarticulated, suggesting that biotic factors, like fish feeding and bacterial decomposition, were contributing to the dispersal of elements.

*Proteopithecus* is a pivotal taxon in the interpretation of early anthropoid phylogeny. The postorbital closure of this primate is well documented (Simons 1997). Unlike all extant Old World anthropoids, it preserves a primitive dental formula of 2-1-3-3, retained today by most New World monkeys. The upper molars show a primitive trigon, relatively bunodont cusps, and a distinct hypocone rising from the distolingual cingulum. *Proteopithecus* has been interpreted as being generalized enough to have given rise to platyrrhines (Kay and Williams 1994). *Proteopithecus* will probably continue to serve as an empirical foil against competing ideas about the basal anthropoid radiations for sometime to come.

Other three-premolaried anthropoids from the Fayum’s Eocene levels include *Arsinoea*, an enigmatic taxon known only from a single jaw, and *Serapia*, an extremely bunodont species that may be related to an otherwise later radiation of primates called parapithecids (see below). An undoubted member of the parapithecid clade, *Qatrania*, is also known from quarry L-41 (Simons et al. 2001). Together, these Fayum three-premolaried primates provide evidence for a diverse radiation of basal, pre-catarrhine anthropoids in Africa. Additional finds from elsewhere in Africa may also belong to this radiation. *Algeripithecus* and *Tabelia* are tiny primates known by isolated teeth from Algeria, possibly of Middle Eocene age (Godinot 1994).

The best-known representatives of three-premolaried Old World anthropoids are Early Oligocene species of the Parapithecidae, known from the upper stratigraphic levels of the Fayum, Egypt. *Apidium phiomense* is a *Saimiri*-sized frugivore that employed arboreal leaping and quadrupedalism. It shows full postorbital closure, fusion of the mandibular symphysis, fused metopic sutures of the frontal bone, large promontory canals of the middle ear, and other distinctly anthropoid-like traits (Fleagle and Kay 1987; Simons 1995). Parapithecids differ from modern anthropoids in having very large olfactory bulbs and relatively small brains. The teeth of this group present various odd specializations. *Apidium* has a central conid on the lower molars and very low molar relief. Its close relative *Parapithecus* lacked adult lower incisors, a situation unique among
primates. The two adult canines erupted side-by-side up through the alveoli of the deciduous incisors. A more recently described cranium of Parapithecus indicates that it did retain adult upper incisors and that, in most respects, it resembles Apidium in cranial morphology (Simons 2001). Postcranially, Apidium is characterized by an extensive ligamentous joint between the tibia and fibula, which suggests a reliance on leaping, but not direct derivation from a fused tibia-fibula such as that of tarsiids. At the same time, the tarsal bones are short, like those of later anthropoids, not elongated like those of leaping omomyids, bushbabies, tarsiers.

The phylogenetic implications of the odd assemblage of character states in Apidium have been thoroughly explored (Fleagle and Kay 1987). Interpretations that preceded the discovery of the Eocene anthropoids typically placed parapithecids as the sister group of a combined catarrhine-platyrrhine clade, but the precise branching relationships among basal anthropoid lineages has become murkier now, although precise hypotheses have been put forth (Ross et al. 1998). All known anthropoid lineages are ancestrally more primitive than what would have been interpreted from parsimony analyses, indicating very high rates of parallelism among lineages, confounding use of parsimony analyses, which will take primitive members of lineages and cast them out as sister taxa.

### 3.7.2 Early catarrhines

Nowhere is the parallelism problem more evident than in the interpretation of two-premolared anthropoids from the Late Eocene. While having a catarrhine dental formula and postorbital closure, these primates are exceedingly primitive in other respects, lacking even a fused mandibular symphysis. One interpretation of this is that the two-premolared condition evolved in more than one basal anthropoid lineage (Ross et al. 1998). A potential problem with this interpretation is that there is considerable continuity up through the Fayum section that documents the acquisition of catarrhine dental and postcranial traits (Rasmussen et al. 1998; Seiffert et al. 2000; Seiffert and Simons 2001). Another possible interpretation is that the true catarrhine lineage really did originate at a point before the acquisition of mandibular fusion and other putative anthropoid traits and that parallelism between platyrrhines and catarrhines is rampant.

The putative catarrhine taxa in question, from primitive to derived, are: Catopithecus, Oligopithecus, Moeripithecus, Propliopithecus, and Aegyptopithecus. The first three are also known by unique species found in coastal deposits in Oman that lie near the Eocene–Oligocene boundary (Gheerbrant et al. 1995;
Thomas et al. 1999). The latter two, known from the Early Oligocene of Egypt, are widely accepted as basal catarrhines. *Catopithecus* is known from several crania and a few limb elements (Simons and Rasmussen 1996; Seiffert and Simons 2001) (*Figure 3.6*) and was a small, callitrichine-sized primate. The first lower molar preserves a paraconid; the upper molars have slight hypocones. The cheek teeth have a decidedly prosimian cast about them and in fact, before crania of *Catopithecus* were found, a long-standing debate concerned whether the teeth of related *Oligopithecus* were prosimian or

![Figure 3.6](image)

The Late Eocene catarrhine *Catopithecus* is represented by several crushed crania. The lower image shows one of the least crushed fragments, a lower face with all the upper teeth intact. Note the large premaxilla, the deep face, and the catarrhine dental formula. The incisors are not naturally so procumbent but have been distorted by crushing. The top image is a reconstruction featuring the postorbital region, which can be examined at various angles on several of the crushed specimens, indicating that *Catopithecus* had modern-type anthropoidean eye sockets. (From Simons and Rasmussen 1996)
anthropoid. The canines of *Catopithecus* are proportionally large in diameter and they project beyond the occlusal plane. The incisors are small and spatulate. There is sexual dimorphism in body size and canine size. The humerus primitively retains an entepicondylar foramen but displays catarrhine-like translation of the distal articular surfaces (Seiffert et al. 2000). *Catopithecus* is the best known of all Eocene anthropoids.

At the other end of the morphological and stratigraphic spectrum is *Aegyptopithecus*, a larger-bodied, heavily built frugivore with fused mandibular symphyses, loss of paraconids, large cuspathe hypocones, and bunodont, apelike molar features (Simons 1987; Rasmussen 2002). The limbs are robust and have a prosimian aspect to them in some ways (Fleagle and Simons 1982) (Figure 3.7). Unlike modern catarrhines, *Aegyptopithecus* lacks a tubular ectotympanic, retains an entepicondylar foramen, and has a very small, prosimian-sized brain. Despite these primitive features, which probably require that the derived character states evolved in parallel in platyrrhines and catarrhines, most researchers readily accept *Aegyptopithecus* as a catarrhine postdating the divergence from platyrrhines. Most
balk, however, at accepting the much higher rates of parallelism required if *Catopithecus* is a catarrhine.

A final Oligocene catarrhine is *Kamoyapithecus* from the Late Oligocene of northern Kenya (Leakey et al. 1995). The dental specimens on which this taxon is based are not well preserved and have suffered significant occlusal wear. While in many ways they resemble, in a general sense, the typical Miocene ape molar pattern, they do display an occlusal outline that is short mesiodistally and broad buccolingually, a shape also typical of the Early Oligocene *Propliopithecus* and *Aegyptopithecus*.

### 3.7.3 Early platyrrhines

The only fossil primates of Oligocene age known from South America come from the Salla beds of Bolivia. These deposits, which have yielded a small handful of primate teeth and jaws, fall chronologically in the Deseadan, or latest Oligocene, probably older than 25 Ma (MacFadden et al. 1985; Naeser et al. 1987). The morphological remains of the Late Oligocene platyrrhines can be evaluated and compared in any number of ways, but the single most important fact to come out of them is that primates were present in the isolated South American continent at that time. Their origin and mode of transport to South America remains a mystery, despite a lively literature arguing specificity of particular rafting routes on one or another ocean current, or stepping stones along one or another speculative island chain.

The morphology of the teeth of *Branisella*, the best-known Deseadan primate (and depending on taxonomic argument, perhaps the only one) remains fairly enigmatic. It shows resemblances to some modern clades of platyrrhines, but those similarities may be primitive. It also shows a remarkable resemblance in certain ways to the teeth of *Proteopithecus* of the Fayum’s Late Eocene beds (Takai et al. 2000). Whether the shared attributes provide evidence for a specialized clade containing *Branisella, Proteopithecus*, and perhaps a modern group like callitrichines, or whether the resemblances are primitive for basal, closed-septum anthropoids, is an interesting subject requiring further research. Probably the most conservative current interpretation would be that *Branisella* reflects the morphology of Eocene *Proteopithecus* because they were recently derived from a common ancestor, in which case their shared attributes might provide a fair amount of information about the basal anthropoid radiation. At the same time, they differ from each other in age by 10 Ma or so, and in geography by half a planet or so, which might generate concern that any connect-the-dots mentality is too enthusiastic.
3.8 True strepsirhines

Modern lemurs, lorises, bushbabies, sifakas, mouse lemurs, and aye-ayes are not just a bunch of leftover prosimians but are a cohesive clade that shared a common ancestor relative to all other known living primates (Yoder et al. 1996; Yoder 1997; Rasmussen and Nekaris 1998). We have more confidence in this clade than we do in Haplorhini. Finding true strepsirhines in the Early Tertiary record has proven to be difficult. Most Eocene taxa classified as strepsirhines are placed there in a paraphyletic sense.

Since the last general view of the fossil evidence pertaining to strepsirhine origins (Rasmussen and Nekaris 1998), several important finds have been made. The most important of these is the discovery of two new primate genera, Kanisia and Saharagalago, from Middle to Late Eocene beds in the Fayum, Egypt, at stratigraphic levels significantly older than quarry L-41 (Martin 2003; Seiffert et al. 2003). Both are represented by a number of isolated teeth. One tooth allocated to Kanisia is the canine of a tooth comb, complete with fine striations caused by grooming hair. This is the earliest fossil record of the tooth comb. Saharagalago is represented by cheek teeth that are remarkably similar to those of modern galagines, which has led to the suggestion that the lorisine-galagine split had already occurred by this date in the Eocene (Seiffert et al. 2003). Younger fossils from the Fayum representing the taxon Wadilemur have also been interpreted as lorisoid (Seiffert et al. 2005b). The new finds are very important for confirming that a true strepsirhine clade was present in Africa and evolving in parallel to “lemur-like” adapoids of the northern continents.

A peculiar primate from quarry L-41 has been identified as an aberrant offshoot of the strepsirhines: Plesiopithecus teras, known by jaws and a crushed cranium (Simons and Rasmussen 1994) (Figure 3.8). The primate has very loris-like lower molars and premolars, and a large, elongated, procumbent anterior tooth that may be a canine. This tooth resembles the canine of the tooth comb but is much larger, and there is no trace of the other anterior teeth (the tooth may be an incisor with the canines missing). The discovery of Kanisia and Saharagalago proves that there is great time depth in the African strepsirhine record, enough to evolutionarily generate a form like Plesiopithecus.

Other African primates that may be strepsirhines include an assemblage of small forms that are cheirogaleid like in their known cheek teeth. They also resemble small adapoids such as European Anchomomys. A detailed comparison of cheirogaleids and anchomomyins in the context of these tiny African primates is provided by Gheerbrant et al. (1993). The taxa in question include Omanodon and Shizaradon from near the Eocene–Oligocene boundary in Oman and a primate referred to Anchomomys from Late Eocene of the Fayum. Whether these prove to be more closely allied with adapoids or with true strepsirhines,
they document that at the time there did exist primates that were ecomorphologically similar to cheirogaleids in African mammal communities.

A similar, small-bodied, cheirogaleid-like primate has been found in the Eocene of Pakistan (Marivaux et al. 2001). While the researchers who described that material placed the new taxon, *Bugtilemur*, within the lemuriform clade close to cheirogaleids, it seems more likely that affinities with the contemporary tiny African primates should be considered. Our understanding of all of these vexing, little mouse-lemur-like taxa would obviously benefit from additional material. As in the case of eosimiids, only future finds can really cement the place of these taxa into a confident phylogenetic framework.

**Acknowledgments**

I thank the editors for inviting me to contribute to this volume. I also gratefully acknowledge the colleagues who have sent me casts of important fossils that I would otherwise not get the chance to examine, with special thanks to Gregg Gunnell, Chris Beard, Emmanuel Gheerbrant, and Prithijit Chatrath. I am...
indebted to Elwyn Simons and Prithijit Chatrath for always sharing with me a few of their annual new discoveries in the Fayum and for their invitations to be involved in the Fayum research. For practical help with the manuscript and the figures, I thank Hilary Brazeal.

4 Fossil Record of Miocene Hominoids

David R. Begun

Abstract

Hominoids, or taxa identified as hominoids, are known from much of Africa, Asia, and Europe since the Late Oligocene. The earliest taxa, from Africa, resemble extant hominoids but share with them mainly primitive characters. Middle and Late Miocene taxa are clearly hominoids, and by the end of the Middle Miocene most can be attributed to either the pongine (Pongo) or hominine (African ape and human) clade. Interestingly, there is no fossil record of the hylobatid clade (gibbons and siamangs). Miocene hominoids experienced a series of dispersals between Africa, Europe, and Asia that mirror those experienced by many other contemporaneous land mammals. These intercontinental movements were made possible by the appearance of land bridges, changes in regional and global climatic conditions, and evolutionary innovations. Most of the attributes that define the hominids evolved in the expansive subtropical zone that was much of Eurasia. Hominines and pongines diverge from each other in Eurasia, and the final Miocene dispersal brings the hominine clade to Africa and the pongine clade to Southeast Asia. Having moved south with the retreating subtropics, hominines and pongines finally diverge in situ into their individual extant lineages.

4.1 Introduction

Nonhuman fossil hominoids represent a highly diverse and successful radiation of catarrhine primates known from many localities ranging geographically from Namibia in the South, Germany in the North, Spain in the West, and Thailand in the East, and temporally from Oligocene deposits in Kenya to the Pleistocene of China (Figure 4.1). More than 40 genera of nonhuman hominoids are known (Table 4.1), probably a small percentage of the total number that have existed. Given the focus of these volumes on ape and especially human evolution, this survey of the fossil record of Miocene hominoids will concentrate on taxa that most or all researchers agree are hominoid and in particular on taxa that are most informative on the pattern and biogeography of modern hominoid origins.
4.1.1 What is a hominoid?

Most of the fossil taxa attributed to the Hominoidea or the Hominidea (new rank, Table 4.2) in this chapter are known to share derived characters with living hominoids. Because the two living families of the Hominoidea, Hylobatidae and Hominidae, share characters that are either absent or ambiguous in their development in *Proconsul* and other Early Miocene taxa, a new rank is proposed here to express the monophyly of the Hominoidea and the monophyly of catarrhines more closely related to extant hominoids than to any other catarrhine. The magnafamily Hominidea (a rank proposed in a work on perissodactyl evolution [Schoch 1986]) unites Proconsuloidea with Hominidea to the exclusion of other catarrhines. This differs from Harrison’s use of the term proconsuloid that he sees as referring to the sister taxon to cercopithecoids and hominoids (Harrison 2002).

Oligo. = Oligocene, e M = Early Miocene, e–m M = Early–Middle Miocene, m M = Middle Miocene, m–l M = Middle–Late Miocene, I M = Late Miocene, K/U = Kenya and Uganda, H/S = Hungary and Spain.

<sup>1</sup>These 40 genera include taxa from the Oligocene and Early Miocene that share mainly primitive characters with the Hominidea but that appear to be derived relative to Pliopithecoids and Propliopithecoids.

<sup>2</sup>Material briefly described by part representation. Dental = mainly isolated teeth; Dental, mandible, maxilla = known only from these parts; Craniodental fragments = teeth and few cranial fragments; Craniodental = larger samples of more informative cranial material; Cranial, dental, postcrania = good samples from each region; ( )+ = very good representation of parts in parentheses.

<sup>3</sup>Unclear attribution to Hominidea.

<sup>4</sup>Large taxon possibly distinct from *Proconsul*.

<sup>5</sup>*Proconsul* from later Early Miocene localities in Kenya is likely to be distinct from earlier Miocene *Proconsul* type material.

<sup>6</sup>Middle Miocene samples attributed to this taxon are more fragmentary and may not be congeneric.

<sup>7</sup>*Ardipithecus kadabba*. 
A few taxa are included in this review if they are too poorly known to preserve unambiguous hominoid synapomorphies but closely resemble other better-known fossil hominoids. In general, fossil and living hominoids retain a primitive catarrhine dental morphology. This makes it difficult to assign many fossil taxa to the Hominidea since a large number are known only from teeth and small portions of jaws. Dentally, the most primitive Hominidea differ only subtly from extinct primitive catarrhines (propliopithecoids and pliopithecoids) (Figure 4.2, node 1). Propliopithecoids (Propliopithecus, Aegyptopithecus) are usually smaller and have much more strongly developed molar cingula, higher cusped premolars, and smaller incisors and canines (Begun et al. 1997; Rasmussen 2002). Pliopithecoids (Pliopithecus, Anapidicus) are also generally smaller and have molars with more strongly expressed cingula, more mesial protoconids,
and relatively small anterior teeth (Begun 2002). However, the differences between Late Miocene hominids and Late Miocene pliopithecoids are more marked than between Early Miocene Hominidea and pliopithecoids, making defining features less than clear-cut. Cranially Hominidea have a completely ossified tubular ectotympanic, which distinguishes them from both propliopithecoids and pliopithecoids but not from cercopithecoids. However, few Miocene Hominidea fossils preserve this region. Hylobatids, cranially the most primitive extant hominoid, share many features found in short-faced Old and New World monkeys, again making it difficult to tease out synapomorphies. Hominoids show a tendency to expand the length and superoinferior thickness or robusticity of the premaxilla, with increasing overlap with the palatine process of the maxilla over time, but once again this is not present in hylobatids or early well-preserved specimens of Proconsul, for example (Begun 1994a). Only one specimen of Early Miocene Hominidea is complete enough to say much about the brain, and there are no unambiguous synapomorphies linking it to hominoids. The brain of Proconsul is similar relative to body size to both hylobatids and papionins, the Old World monkeys with the largest brains, and the sulcal pattern, while debatable, lacks most if not all hominoid features (Falk 1983; Begun and Kordos 2004). Like hylobatids, most cercopithecoids, and most mammals other than hominids, a portion of the brain of Proconsul occupied a large subarcuate fossa. Cranial and dental evidence also suggests that Proconsul was moderately delayed in terms of life history, another similarity with extant hominoids (Kelley 1997, 2004).

Postcranially, Proconsul more clearly represents the ancestral hominoid morphotype, though this too is the subject of debate. Proconsul fossils exhibit hominoid attributes of the elbow, wrist, vertebral column, hip joint, and foot, though in all cases these are subtle and disputed (Beard et al. 1986; Rose 1983, 1988, 1992, 1994, 1997; Ward et al. 1991; Ward 1993, 1997; Begun et al. 1994; but see Harrison 2002, 1987). Proconsul has a suite of characters consistent with the hypothetical ancestral morphotype of the hominoids, and it should not be surprising that these are poorly developed at first, only to become more refined as hominoids evolve. In comparison to the hominoid outgroup (cercopithecoids), we can expect the earliest hominoids to show subtle indications of increased orthogrady, positional behaviors with increased limb flexibility and enhanced grasping capabilities and no tail, generalized (primitive) dentition, encephalization at the high end of extant cercopithecoids of comparable body mass, and life history variables closer to extant hominoids than to extant cercopithecoids. Proconsul has all of these attributes.

If these are the features that define the Hominidea, which taxa among Miocene fossil catarrhines are not Hominidea? Even the earliest cercopithecoids
(victoriapithecids) are easily distinguished from hominoids (Benefit and McCrossin 2002). Pliopithecoids, often grouped with the “apes,” are even more distantly related. They are clearly stem catarrhines lacking synapomorphies of all crown catarrhines including Proconsul and Victoriapithecus (Begun 2002). The most informative among these synapomorphies are the tubular ectotympanic and the entepicondylar groove (often referred to as the absence of an entepicondylar foramen). In the following sections, I will summarize current knowledge of the Miocene Hominidea, focusing on well-known taxa that serve to illustrate important events in hominoid evolutionary history (Figure 4.2).

4.2 Origins of Hominidea

It is likely that hominoids originated in Africa from an ancestor that, if known, would be grouped among the Pliopithecoida. Pliopithecoids, currently known only from Eurasia, share with all catarrhines the same dental formula and possibly with crown catarrhines a reduction of the midface, subtle features of the molar dentition, and a partial ossification of the ectotympanic tube (Begun 2002). The presence of pliopithecoids in Africa is suggestive but remains to be demonstrated (Andrews 1978; Begun 2002). The oldest and most primitive catarrhine that can lay claim to hominoid status however is African (Table 4.1). Kamoyapithecus, from the Oligocene of Kenya, differs from other Oligocene catarrhines (propliopithecoids) in being larger and having canines and premolars that more closely resemble Miocene hominoids than Oligo-Miocene non-hominoids (Leakey et al. 1995). Only craniodental material of Kamoyapithecus has been described, and it is so primitive as to make attribution to the Hominoidea difficult. Though it would fail to fall among the Hominoidea in a quantitative cladistic analysis due to its fragmentary preservation and primitive morphology, it makes in my view a good hominoid precursor.

4.3 Proconsuloidea

4.3.1 Proconsul

The superfamily Proconsuloidea, as defined by Harrison (2002), includes many mainly Early Miocene taxa. As noted, in this chapter a number of taxa from this group are interpreted to represent primitive Hominidea or hominoids. A hypothetical ancestral morphotype for the Hominidea is given in Figure 4.2 (node 1). Node 1 represents the bifurcation of Proconsul from hominoids with more
apparent synapomorphies to living hominoids. *Proconsul* as described here is based mainly on the sample from Rusinga Island, Kenya along with other localities of the same age. These include the species *Proconsul heseloni* (Walker et al. 1993) and *Proconsul nyanzae* (Le Gros Clark and Leakey 1950). The type
specimen of *Proconsul africanus* (Hopwood 1933) is from Koru, which is 1-to 2-Myr older, as is the type of *Proconsul major* (Le Gros Clark and Leakey 1950) from Songhor (Drake et al. 1988). There is evidence that the younger species of *Proconsul* that are the basis of the description here belong to a different genus from the older type sample (see below). However, as this is not the appropriate venue to name a new genus, I will follow convention and refer to the Rusinga sample as *Proconsul*.

### 4.3.1.1 Postcranial morphology

*Proconsul* and other proconsuloids are defined by a large number of characters. *Proconsul* is a generalized arboreal quadruped but is neither monkey-like nor apelike (Rose 1983). The following summary is mainly from Rose (1997), Ward (1997), and Walker (1997). In addition to the characters noted that emphasized its hominoid affinities, *Proconsul* has limbs of nearly equal length, with scapula positioned laterally on the thorax and the ovoid and narrow glenoid positioned inferiorly, as in generalized quadrupeds. The thorax is transversely narrow and deep superoinferiorly, and the vertebral column is long and flexible, especially in the lumbar region. The innominate is long with a narrow ilium and an elongated ischium. The sacrum is narrow, and its distal end indicates that it articulated with a coccygeal and not a caudal vertebra, in other words *Proconsul* had a coccyx and not a tail (Ward et al. 1991).

In the details of limb morphology, *Proconsul* also combines aspects of monkey and ape morphology. *Proconsul* forelimbs lack the characteristic elongation of ape forelimbs. The humeral head is oriented posteriorly relative to the transverse plane and the humeral shaft is convex anteriorly, both of which are consistent with the position of the glenoid fossa and the shape of the thorax. The distal end of the humerus lacks the enlargement of the capitulum and trochlea and other details of the hominoid elbow, but it does have a narrow zona conoidea and a mild trochlear notch. The medial epicondyle is also more posteriorly oriented as in monkeys. The proximal ends of the radius and ulna are consistent with the morphology of the distal humerus. The radial head is small and ovoid, the ulnar trochlea is narrow and has a poorly developed keel, and the radial notch is positioned anteriorly. The ulna also has a large olecranon process. All of these features are consistent with generalized pronograde (above branch) quadrupedalism as opposed to antipronograde (suspensory or below branch) (see Ward Volume 2 Chapter 6).

Distally, the radial carpal surface is flat and articulates mainly with the scaphoid. The ulnar head is comparatively large with a long and prominent
styloid process that articulates directly with the pisiform and triquetrum, unlike living hominoids, which have greatly reduced ulnar styloids and no contact with the carpals. The carpals are small transversely. The scaphoid is separate from the os centrale and the midcarpal joint is narrow. The hamate hamulus is small, and the surface for the triquetrum is flat and mainly medially oriented (Beard et al. 1986). The metacarpal surfaces of the distal carpals are small and comparatively simple as are the corresponding surfaces on the metacarpal bases. The metacarpals are short and straight and their heads transversely narrow. The proximal ends of the proximal phalanges are slightly dorsally positioned as in palmigrade quadrupeds. All the phalanges are short and straight compared to apes, though secondary shaft features, in particular of the proximal phalanges, suggest powerful grasping (Begun et al. 1994).

The hindlimbs of *Proconsul* are also dominated by monkey-like characters. The long bones are long and slender. The femoral head is small compared to apes, but its articulation with the acetabulum indicates more mobility compared to most monkeys. The feet of *Proconsul* are monkey-like in their length to breadth ratio (they are narrow compared to great ape feet). *Proconsul* tarsals are elongated relative to breadth and the metatarsals long compared to the phalanges. Like those of the hands, the foot phalanges of *Proconsul* are straighter and less curved than in apes but with more strongly developed features related to grasping than in most monkeys. The hallucial phalanges are relatively robust, suggestive of a powerfully grasping big toe. Body mass estimates for the species of *Proconsul*, based mainly on postcranial evidence, range from about 10 to 50 kg (Ruff et al. 1989; Rafferty et al. 1995).

### 4.3.1.2 Craniodental morphology

As noted, *Proconsul* has a moderate amount of encephalization (comparable to hylobatids and papionins), a short face with a fenestrated palate (Figure 4.3), a smoothly rounded and somewhat airorhynchous face (Figure 4.4), and a generalized dentition. Morphologically, the dentition is consistent with a soft fruit diet, and microwear analysis suggests the same (Kay and Ungar 1997). The somewhat enlarged brain of *Proconsul* implies a degree of life history delay approaching the hominoid pattern (Kelley 1997, 2004).

One aspect of the cranium of *Proconsul* that has received some attention is the frontal sinus. Walker (1997) interprets the presence of a frontal sinus in *Proconsul* to indicate its hominid status, citing the presence of large frontal sinuses in some great apes. Other researchers have suggested that the frontal
sinus is a primitive character, as it is found in *Aegyptopithecus* and many New World monkeys (Andrews 1992; Rossie et al. 2002). The confusion stems from the use of one term to describe several different characters. As Cave and Haines (1940) noted long ago, frontal sinuses in primates have various ontogenetic origins, and it is likely that they are not homologous across the primates. New World monkeys have frontal sinuses that are outgrowths from the sphenoid sinus, as is also the case for hylobatids. On the other hand, *Pongo*, which occasionally has a frontal sinus, derives it from the maxillary sinus. African apes and humans normally have large frontal sinuses derived from the ethmoidal sinuses. “Frontal sinuses” then are actually three different characters, frontosphenoidal sinuses, frontomaxillary sinuses, and frontoethmoidal sinuses.

While it is possible to establish the ontogenetic origin of a pneumatized frontal bone in living primates, it is more difficult in fossil primates. However, the placement and size of the frontal sinuses correlate very well with their ontogenetic

**Figure 4.3**

Midsagittal cross section of a number of Hominidea palates showing some of the features described in the text. *Proconsul* has a small premaxilla and a fenestrated palate (large foramen and no overlap between the maxilla and premaxilla). *Nacholapithecus* has a longer premaxilla with some overlap. It is similar to *Afropithecus* and conceivably could be the primitive morphotype for the Hominidae. *Pongo* and *Sivapithecus* have a similar configuration but with further elongation and extensive overlap between the maxilla and premaxilla, producing a smooth subnasal floor. Hominines have robust premaxillae that are generally shorter and less overlapping than in *Sivapithecus* and *Pongo*. *Dryopithecus* is most similar to *Gorilla*, which may represent the primitive condition for hominines. *Pan* and *Australopithecus* have further elongation and overlap, but the configuration differs from *Pongo*. This morphology is suggested to be an important synapomorphy of the *Pan/Homo* clade (Begun 1992b). Modified from Begun (1994)
origin, offering a protocol for identifying the specific type of frontal sinus present in a fossil (Begun 1994a). Frontosphenoidal sinuses invade large portions of the frontal squama but not the supraorbital or interorbital regions. Frontomaxillary sinuses are infrequent in *Pongo*, but when they occur they are associated with narrow canals or invaginations connecting the maxillary sinuses to a small pneumatization of the frontal via the interorbital space. In African apes and humans, the frontoethmoidal sinuses arise from a spreading of the ethmoidal air cells in the vicinity of nasion, resulting in large pneumatizations from below nasion into the supraorbital portion of the frontal. The actual amount of frontal pneumatization is variable, while the presence of a large sinus around nasion is constant. Therefore, while we cannot observe the development of frontal pneumatization in fossil primates, and we do not have adequate ontogenetic series to directly reconstruct this growth, we can infer the type of frontal pneumatization from its position, extent, and connection to the source sinus. In *Proconsul*, as in hyllobatids, New World monkeys, and *Aegyptopithecus*, the frontal pneumatization is
extensive and occupies the frontal squama, consistent with a frontosphenoidal sinus. Thus, the “frontal sinus” in Proconsul is a primitive character, as suggested by Andrews (1992), but for different reasons. The frontal pneumatization of Dryopithecus, on the other hand, conforms to the pattern seen exclusively in African apes and humans (see below).

In summary, Proconsul was an above branch mid- to large-sized catarrhine with a diet dominated by soft fruits and a somewhat slower life history than cercopithecoids. Encephalization may imply other similarities to hominoid behavioral or social ecology, or it may simply be a consequence of relatively large body mass and/or a slower life history (Kelley 2004; Russon and Begun 2004). The slightly enhanced range of motion in Proconsul limbs may imply some degree of orthogrady, or it may be a consequence of lacking a tail or of large body mass in an arboreal milieu, or some combination of all three (Beard et al. 1986; Begun et al. 1994; Kelley 1997).

4.3.2 Other possible proconsuloids

A number of taxa are regarded by many researchers as having a probable close relationship to Proconsul. The three with the best evidence for affinities to the proconsuloids are Proconsul sensu stricto, Micropithecus, and Samburupithecus. As noted, the type species of the genus Proconsul is P. africanus. P. africanus and P. major, which are both older than Proconsul from Rusinga, are also more primitive and lack synapomorphies shared by Proconsul from Rusinga and other hominoids (see below). Other taxa listed in Table 4.2 are either more likely to be hominoids given similarities to known hominoids (Rangwapithecus, Nyanzapithecus, Mabokopithecus) or they are so primitive or poorly known as to cast doubt on their magnafamily status.

4.3.2.1 Proconsul sensu stricto

The older species of Proconsul sensu stricto from Songhor and Koru (P. africanus and P. major) probably represent a different genus from P. heseloni and P. nyanzae, the samples on which the descriptions of Proconsul presented here are based. A new genus would replace P. heseloni and P. nyanzae, as P. africanus has priority. Proconsul sensu stricto from Songhor and Koru has elongated postcanine teeth, more strongly developed cingula, upper premolars with strong cusp heteromorphy and conical, individualized molar cusps, all of which suggest that the older species are in fact more primitive. The two older species differ from each other
only in size. Postcrania attributed to Proconsul from the older Proconsul sensu stricto localities are distinct from postcrania from the younger Proconsul localities such as Rusinga, in details that have been correlated to paleoecological differences (Andrews et al. 1997). While sufficiently similar to the better-known younger Proconsul sample to warrant placing both in the same superfamily, the more modern morphology of the younger Proconsul sample will almost certainly require taxonomic recognition.

Ugandapithecus, a recently named genus based on the sample of P. major, adds to the confusion (Senut et al. 2000). P. africanus is smaller than “Ugandapithecus” major but is morphologically closer to it in the attributes noted above. Thus, while Ugandapithecus is probably a junior subjective synonym of Proconsul sensu stricto, it turns out that Proconsul as traditionally defined probably does represent more than one genus. Senut et al. (2000) have suggested that large-bodied hominoids from Moroto, in Uganda, may also be attributed to Ugandapithecus (hence the name, though the type is from Kenya), that is, P. major, calling into question the interpretation that hominoid cranial and postcranial fossils from Moroto belong to one taxon (Morotopithecus). However, the evidence for more than one large hominoid genus at Moroto is not strong (see below).

4.3.2.2 Micropithecus

Micropithecus (Fleagle and Simons 1978) is a small catarrhine with comparatively broad incisors and long postcanine teeth with low cusps and rounded occlusal crests. The cingula are less strongly developed than most other Early Miocene catarrhines. Males and females exhibit marked size dimorphism. Comparisons to living catarrhines suggest a body mass of about 34.5 kg (Harrison 2002). While Harrison (2002) considers this taxon to be even more distantly related to the Hominoidea than are the Proconsuloida, the subtly more modern features of the dentition suggest that it may belong to the Proconsuloida. Fleagle and Simons (1978) in fact attribute Micropithecus to the Hominoidea, although as noted the features shared with hominoids are very subtle. If Micropithecus is a proconsuloid, as suggested here, it would indicate that the proconsuloids were quite diverse in body mass, as is the case in all catarrhine superfamilies.

4.3.2.3 Samburupithecus

Samburupithecus is another possible proconsuloid, known only from a large maxillary fragment from the Late Miocene of the Samburu region of Kenya
(Ishida and Pickford 1997). Ishida and Pickford (1997) have suggested that Samburupithecus is an early member of the African ape and human clade. However, Samburupithecus retains many primitive characters of the Proconsulidea. These include a low root of the zygomatic processes, a strongly inclined nasal aperture edge, the retention of molar cingula, and thick enamel with high dentine relief (Begun 2001). Samburupithecus is most likely to be a late surviving proconsuloid. Its unusual dental characters (e.g., large molars with individualized cusps separated by deep narrow fissures) are reminiscent of morphological “extremes” found in terminal lineages with long evolutionary histories. Oropithecus, Gigantopithecus, Paranthropus, Daubentonia, and Ekgmowechashala all share with Samburupithecus exaggerated occlusal features compared to other members of their respective clades. The size and occlusal morphology of Samburupithecus that superficially resembles Gorilla (Ishida and Pickford 1997) may be related in part to the fact that both are ends of long phylogenetic branches. In a pattern analogous to long branch attraction in molecular systematics, there is a tendency for separate long isolated lineages to converge in certain aspects of their morphology (Begun 2001). For whatever the reason, in its details Samburupithecus is primitive and more likely to belong to the proconsuloids than the hominoids.

4.4 Early hominoids

4.4.1 Afropithecus

A number of late Early Miocene and Middle Miocene taxa share characters with extant Hominoids and are included here in the Hominoidea. Afropithecus (Leakey and Leakey 1986) is known from several localities in northern Kenya dated to 17–17.5 Ma (Leakey and Walker 1997). Afropithecus shares an increase in premaxillary robusticity and length with most extant hominoids (Figure 4.3). Like many Late Miocene and Pliocene hominids, Afropithecus has very thick occlusal enamel as well. On the other hand, Afropithecus cranial morphology, particularly the morphology of the midface, recalls that of Aegyptopithecus. Thus, as with Proconsul, Afropithecus has a mosaic of primitive and derived characters (Leakey et al. 1991; Leakey and Walker 1997). Leakey and Walker (1997) have suggested that the unusual primitive looking face of Afropithecus may be related to a specialized scerocarp seed predator adaptation. This is functionally consistent with the robust, prognathic premaxilla, large, relatively horizontal incisors, large but relatively low-crowned canines, expanded premolars, thick enamel, and powerful chewing muscles of Afropithecus. A similar set of features
is found in modern primate seed predators such as pithecines. It may be that some of the primitive appearance of the *Afropithecus* face is homoplastic with *Aegyptopithecus*.

A large cranial specimen of *Afropithecus* reveals some information on neurocranial morphology. KNM-WK 16999 preserves a portion of the braincase immediately behind the orbits. Postorbital constriction is very marked as are the anterior temporal lines. These converge to form a pronounced and very anteriorly situated sagittal crest. The small portion of the anterior cranial fossa preserved indicates a cerebrum that was constricted rostrally, lacking the frontal lobe expansion typical of extant and fossil great apes.

*Afropithecus* is similar in size to *Proconsul nyanzae*, based on cranial, dental, and postcranial dimensions (Leakey and Walker 1997). *Afropithecus* postcrania are very similar to those of *Proconsul*, so much so that Rose (1993) found them essentially indistinguishable. The postcranial adaptation, in terms of body mass and positional behavior, is *Proconsul*-like, while the craniodental anatomy is markedly distinct.

Another early hominoid taxon, *Heliopithecus*, is contemporaneous with *Afropithecus* and morphologically very similar, though it is only known from a fragmentary hemimaxilla and a few isolated teeth (Andrews and Martin 1987). Both *Heliopithecus* and *Afropithecus* share characters that are found next in the fossil record in Eurasia, which suggests that *Heliopithecus* and *Afropithecus* taxa may have a closer relationship to late Early Miocene and Middle Miocene hominoids from Europe than do proconsuloids.

### 4.4.2 *Morotopithecus*

*Morotopithecus* is a fossil hominoid from Uganda dated to about 21 Ma by some and 17 Ma by others (Gebo et al. 1997; Pickford et al. 2003). It is best known from a large cranial specimen including most of the palate (Pilbeam 1969). For many years, this specimen was attributed to *Proconsul major*, but it is clear that it and other specimens from Moroto are sufficiently distinct to justify a new genus. *Morotopithecus* is similar in size to *Proconsul major* and larger than *Proconsul nyanzae* and *Afropithecus*. It lacks the distinctive subnasal morphology of *Afropithecus* and has a *Proconsul*-like premaxilla that is short, gracile, and does not overlap the palatine process of the maxilla, resulting in a large incisive fenestration (Figure 4.3). *Morotopithecus* has a broad palate, large anterior teeth, especially the canines, which are tusklike, a piriform aperture broadest about mid way up, and an interorbital space that appears to be relatively narrow, though it is damaged. However, the most important distinction of *Morotopithecus* is the
morphology of the postcrania, which are said to be modern hominoid-like. Newly described specimens of *Morotopithecus* include the shoulder joint, hip joint, and details of the vertebral column. Walker and Rose (1968) described the vertebrae as hominoid-like, which has been confirmed by more recent discoveries and analyses. The glenoid fossa of *Morotopithecus* suggests a more mobile shoulder joint as does the morphology of the hip joint. However, it is the hominoid-like position of the transverse processes of the vertebrae that represents the strongest evidence for the hominid affinities of *Morotopithecus*. The roots of the transverse processes of the lumbar vertebrae of *Morotopithecus* are positioned posteriorly, as in extant great apes, suggesting a stiff lower back and an axial skeleton like that of extant hominoids.

### 4.4.3 Eurasian hominoid origins

As noted, *Heliopithecus* and *Afropithecus* have more robust jaws and teeth than Early Miocene proconsuloids, and this may represent a key adaptation that permitted the expansion of hominoids into Eurasia at about 17 Ma, when during a marine low stand a diversity of terrestrial mammals moved between Africa and Eurasia (Made 1999; Begun 2001; Begun et al. 2003). Toward the end of the Early Miocene, the movement of the southern landmasses northward, combined with a number of other developments (the Alpine and Himalayan orogenies, the earliest appearance the polar ice caps, and the Asian Monsoons), leads to a sequence of connections and barriers to terrestrial faunal exchange (Rögl 1999a, b; Adams et al. 1999; MacLeod 1999; Hoorn et al. 2000; Zhisheng et al. 2001; Guo et al. 2002; Liu and Yin 2002; Wilson et al. 2002). This period of global turbulence affected sea levels between continents cyclically such that for the remainder of the Miocene there would be periodic connections (low stands) and disconnections (high stands) between the continents. At about 17 Ma, a low stand that had permitted the exchange of terrestrial faunas between Eurasia and Africa (the Proboscidean datum) was coming to an end but not before hominoids possibly resembling *Afropithecus* and *Heliopithecus* dispersed from Africa into Eurasia (Heizmann and Begun 2001; Begun 2002, 2004; Begun et al. 2003).

At the end of the Early Miocene, about 16.5 Ma, hominoids of more modern dental aspect first appear in Eurasia. The oldest Eurasian hominoid is cf. *Griphopithecus*, known from a molar fragment from Germany. *Griphopithecus* (Abel 1902) is known mainly from large samples from Turkey of roughly the same age, while the type material is known from a probably later (14–15 Ma) locality, Děvinská Nová Ves, in Slovakia (Heizmann 1992; Andrews et al. 1996; Heizmann and Begun 2001; Begun et al. 2003). cf. *Griphopithecus* from Engelsweis in
Germany is a tooth fragment that has the more modern features of being thickly enameled with low dentine penetrance (tall dentine horns did not project into the thick enamel cap as in *Proconsul* and probably *Afropithecus*). cf. is the designation for a taxon that is similar enough to another taxon for there to be a strong likelihood that they are the same, but with some formally acknowledged uncertainty. *Griphopithecus* is better known from over 1,000 specimens, mostly isolated teeth, from 2 localities in Turkey (Çandır and Paşalar). One species, *Griphopithecus alpani* (Tekkaya 1974) is known from both localities, while a second somewhat more derived taxon is also found at Pasalar (Alpagut et al. 1990; Martin and Andrews 1993; Kelley and Alpagut 1999; Ward et al. 1999; Kelley et al. 2000; Kelley 2002; Güleç and Begun 2003).

*Griphopithecus alpani* has robust mandibles with strongly reinforced symphyses, broad, flat molars with thick enamel, and reduced cingulum development compared to *Proconsul*. It retains primitive tooth proportions (small M1 relative to M2), anterior tooth morphology, and postcanine occlusal outline shape. A few fragments of the maxilla from Pasalar indicate a primitive morphology for the anterior palate (Martin and Andrews 1993). The morphology of *Griphopithecus* molars as well as their microwear indicates a diet allowing the exploitation of hard or tough fruits, though it is not clear if this means simply that they could exploit these resources when needed (a keystone resource) or if they were a favored source of food. Two postcranial specimens, a humeral shaft and most of an ulna, from the younger site of Klein Hadersdorf, Austria, are also similar to *Proconsul* and indicate that *Griphopithecus* was a large bodied above branch arboreal quadruped similar in size and positional behavior to *Proconsul nyanzae* (Begun 1992a).

4.4.4 East African Middle Miocene thick-enamedled hominoids

Shortly after the appearance of *Griphopithecus* in Western Eurasia, dispersals between Eurasia and Africa were interrupted by the Langhian transgression (Rögl 1999a). Following the Langhian, at about 15 Ma, dispersals resumed in a number of mammal lineages, probably also including hominoids (Begun et al. 2003a, b). Hominoids closely similar to *Griphopithecus* in dental morphology appear in Kenya at this time. *Equatorius* is known from 15-Ma localities in the Tugen Hills and at Maboko, both in Kenya. This taxon, previously attributed to *Kenyapithecus*, is very similar to *Griphopithecus* but has a distinctive incisor morphology and reduced cingula, probably warranting a distinct genus status (Ward et al. 1999; Kelley et al. 2000; Ward and Duren 2002; contra Begun 2000,
Equatorius is also known from a good sample of postcrania, including most of the bones of the forelimb, vertebral column, hindlimb long bones, and a few pedal elements (Ward and Duren 2002). Like Grippopithecus, which is much less well known postcranially, Equatorius is similar to Proconsul nyanzae in postcranial size and morphology.

Nacholapithecus (Ishida et al. 1999) is known from deposits of the same age in the Samburu Basin of Kenya (Nakatsukasa et al. 1998). Like Equatorius, Nacholapithecus is known from a relatively complete skeleton, more complete in fact than the best specimen of Equatorius. From this exceptional skeleton, we know that Equatorius is similar to other Middle Miocene hominoids in most aspects of the jaws and teeth but unique in aspects of limb morphology. Kunimatsu et al. (2004) provide evidence that the anterior portion of the palate of Nacholapithecus is hominid-like in its length and degree of overlap with the palatine process of the maxilla (Figure 4.3). This morphology is the principal evidence for the hominoid status of this species. However in its details, the anterior palate of Nacholapithecus is unlike that of hominids (see below).

The postcranial skeleton of Nacholapithecus is similar to other Middle Miocene hominoids in having the general signature of a generalized, palmigrade, arboreal quadruped, but differs from Equatorius, also known from fore and hindlimb, in the enlarged size and robusticity of its forelimb. While not like extant nonhuman hominoids in forelimb length relative to the hindlimb, Nacholapithecus forelimbs are large and powerful, indicating a form of positional behavior emphasizing powerful forelimb grasping (Ishida et al. 2004).

Kenyapithecus (Leakey 1962) is the most derived of the Middle Miocene African hominoids and may be the earliest hominid (Table 4.2). Kenyapithecus is known only from a small sample from Fort Ternan in Kenya, though a second species may be present in Turkey (see below). Like other Middle Miocene hominoids, Kenyapithecus has large flat molars with broad cusps and thick enamel. The maxilla of Kenyapithecus, however, is derived in having a high root of the zygomatic, a probable hominid synapomorphy. While McCrossin and Benefit (1997) believe that Equatorius and Kenyapithecus represent a single species, most researchers have concluded that two genera are present and that Kenyapithecus is derived relative to Equatorius (Harrison 1992; Ward et al. 1999), and that is the view adopted here. As noted, it has been suggested that Kenyapithecus is also present at Pasalar. If so, and if Kenyapithecus is indeed an early hominid, this would date the origin of the hominid family to at least 16 Ma. However, there is a roughly 3 Ma gap between possible Kenyapithecus at Paşalar and the type material from Fort Ternan.

One last Middle Miocene hominoid deserves mention here. Otavipithecus is the only Miocene hominoid known from southern Africa, from the 13-Ma site of
Berg Aukas in Namibia (Conroy et al. 1992). Several specimens have been described, including the type mandible, a frontal fragment, and a few postcrania (Conroy et al. 1992; Pickford et al. 1997; Senut and Gommery 1997). It has been suggested that *Otavipithecus* has affinities to hominids (Conroy et al. 1992; Ward and Duren 2002), but it preserves primitive proconsuloid characters such as a small M₁ compared to M₂, a long M₃, parallel tooth rows, a small space for the mandibular incisors, low P₄ talonid, and tall, centralized molar cusps (Begun 1994b). Singleton (2000) carried out the most comprehensive analysis of *Otavipithecus* and concluded that it may be related to *Afropithecus*, which is broadly consistent with the placement of the taxon in Figure 4.2.

### 4.4.5 Summary of Middle Miocene hominoid evolution

The radiation of Middle Miocene hominoids in Africa was short lived. Having apparently dispersed from Eurasia by about 15 Ma, they are extinct by 12.5–13 Ma. Aside from a few fragmentary specimens that most likely represent the end of the *Proconsul* lineage (Hill and Ward 1988), hominoids would not appear again in Africa until the latest Miocene when they are represented by the earliest known hominins. Given the rarity of hominoid localities in the early Middle Miocene, the biogeographic hypothesis of the dispersal of Middle Miocene hominoids presented here is debatable. It is certainly possible, for example, that Early Miocene *Griphopithecus*-like fossils will be found in Africa that will show that *Equatorius, Nacholapithecus*, and *Kenyapithecus* all evolved *in situ* in Africa and that apparently earlier fossils from Eurasia are either misdated or are early offshoots of this clade with no direct relationship to later hominids (Ward and Duren 2002). However, the evidence as it currently stands supports the scenario presented here to be tested by new discoveries.

### 4.5 Early hominids

While *Kenyapithecus* shares a synapomorphy with the Hominidae (position of the zygomatic root), the first clear-cut hominids are known from Eurasia and share numerous cranial, dental, and postcranial synapomorphies with living hominids. The extant Hominidae is divided into two subfamilies, Ponginae and Homininae, and both are represented by roughly contemporaneous fossil taxa. The earliest hominines are represented by *Pierolapithecus, Dryopithecus*, and *Ouranopithecus*, all with affinities to fossil hominins and extant hominines, and the earliest pongines are represented by *Ankarapithecus, Sivapithecus*, and relatives. Miocene
hominines are known from western Eurasia, while Miocene pongines are known from South and East Asia, reflecting the basic biogeographic division of the two hominid subfamilies today.

### 4.5.1 Fossil pongines

The oldest sample of fossils widely interpreted as pongine is *Sivapithecus* from the middle Chinji formation of Siwaliks of Pakistan (Raza et al. 1983; Rose 1984, 1989; Kappelman et al. 1991; Barry et al. 2002). Specimens referred *Sivapithecus indicus* that are known to come from the middle Chinji formation share characters with later *Sivapithecus* and other hominids including reduced or absent molar cingula, relatively large M1, reduced premolar cusp heteromorphy, long, buccolingually compressed canines, broad based nasal aperture, elongated and robust premaxilla partly overlapping the maxilla and, as in *Kenyapithecus*, a high position to the zygomatic root. They share specifically with later *Sivapithecus* fewer clear-cut characters, such as probably strongly heteromorphic upper incisors (known only from the roots), and broad, flat cusped molars with thick enamel, though these characters are also found in most other Middle and many Late Miocene hominoids. One specimen of Chinji *Sivapithecus*, GSP 16075, represents a portion of the palate with the connection between the maxilla and premaxilla partially preserved. The maxillary–premaxillary relationship is highly diagnostic of *Sivapithecus* and the pongine clade, and the morphology of the Chinji specimen has been interpreted to share characters of this complex (Raza et al. 1983; Ward 1997; Kelley 2002). However, while the specimen does have a relatively elongated, horizontal, and robust premaxilla, the area of the incisive fossa and foramen are not preserved. In the absence of this region, it is difficult to distinguish Chinji *Sivapithecus* from later *Sivapithecus*, including later *Sivapithecus indicus*, to which it is assigned, versus another pongine, *Ankarapithecus*. Resolution of this uncertainty may help to clarify the biogeography of pongine origins (see below).

### 4.5.2 *Sivapithecus*

#### 4.5.2.1 *Sivapithecus* craniodental evidence

Most of the *Sivapithecus* samples, including the best-known specimens with the clearest evidence of pongine affinities, are from younger localities of the Siwaliks of India and Pakistan, dated between 10.5 and 7.5 Ma (Barry et al. 2002). In the
following section, I discuss *Sivapithecus* in some detail because it is in many ways critical to understanding Late Miocene hominoid evolution. Three species are generally recognized in this sample, the best known of which is *Sivapithecus sivalensis* (Lydekker 1879), from localities ranging in age from 9.5 to 8.5 Ma (Kelley 2002). In addition to the characters outlined above, *Sivapithecus sivalensis* is known from a suite of cranial characters strongly indicative of pongine affinities (Pilbeam 1982). These include unfused tympanic and articular portions of the temporal bone, a posterosuperiorly directed zygomatic arch with deep temporal and zygomatic processes, vertically oriented frontal squama, supraorbital costae or rims, a narrow interorbital space, elongated nasal bones, tall, narrow orbits, wide, anteriorly oriented zygoma, narrow, pear-shaped nasal aperture, externally rotated canines, long, horizontally oriented nasoalveolar clivus that is curved along its length but flat transversely and a subnasal region with the posterior pole of the premaxilla merging into the anterior edge of the maxillary palating process to form a flat, nearly continuous subnasal floor (Figure 4.3) and a strongly concave facial profile from glabella to the base of the nasal aperture. *Sivapithecus* is also likely to have been airorhynchous (having a dorsally deflected face), as in *Pongo* (Figure 4.4). All of these and other characters are described in more detail in Ward and Pilbeam (1983), Ward and Kimbel (1983), Ward and Brown (1986), Brown and Ward (1988), Ward (1997). *Sivapithecus sivalensis* is not identical to *Pongo* in cranial morphology however, even if the similarities are striking and detailed. *Sivapithecus sivalensis* is more robust than similarly size (female) *Pongo* in features related to the masticatory apparatus, including aspects of the zygomatic and temporal bones, maxillary robusticity, and molar morphology. The molars in particular are easily distinguished from those of *Pongo* in having thicker enamel and in lacking the complex pattern of crenulations seen in unworn *Pongo* molars. However, overall the number of derived characters shared with *Pongo* is quite high (Ward 1997; Kelley 2002).

*Sivapithecus indicus* (Pilgrim 1910) is the oldest species, and if the middle Chinji fossils are included, it would range from 12.5 to 10.5 Ma (Kelley 2002). It is the smallest species, at least in terms of dental size, and appears to have a slightly shorter nasoalveolar clivus or premaxilla compared to *Sivapithecus sivalensis* (see above). *Sivapithecus parvada* (Kelley 1988) is considerably larger than the other species and is known from the Nagri formation locality Y311, about 10 Ma. *Sivapithecus parvada* males are about the dental size of female gorillas. The upper central incisors are especially long mesiodistally, the M₃ is larger than the M₂, the premolars are relatively large, and the symphysis of the mandible is very deep (Kelley 2002).
4.5.2.2 *Sivapithecus* postcrania

*Sivapithecus* postcrania have been described in many publications (Pilbeam et al. 1980, 1990; Rose 1984, 1986, 1989; Spoor et al. 1991; Richmond and Whalen 2001; Madar et al. 2002). They combine a mixture of characters, some suggesting more palmigrade postures and others suggestive of more suspensory positional behavior. This has been interpreted by some to indicate that *Sivapithecus* is more primitive than any living hominoid, all of which, even humans, share numerous characters of the shoulder and forelimbs related to suspensory behavior or an ancestry of suspensory behavior (Pilbeam 1996, 1997; Pilbeam and Young 2001, 2004). This view, also shared by McCrossin and Benefit (1997), has dramatic implications for the interpretation of the hominoid fossil record. All Late Miocene hominoids, including *Sivapithecus*, share many characters of the cranium and dentition with living hominoids. If *Sivapithecus* is more primitive than extant hominoids, given its apparently primitive postcrania, then all the apparently derived hominid features of *Sivapithecus* would have evolved in parallel in *Sivapithecus*, and as these authors suggest, by extension in all Late Miocene hominoids (*Oreopithecus*, *Dryopithecus*, *Ouranopithecus*, and *Lufengpithecus*, etc.). These parallelisms include not only craniodental morphology but also details of life history and as it turns out, many postcranial characters as well. In fact, the apparently primitive characters of *Sivapithecus* postcrania are small in number compared to the large number of clearly derived hominid characters from throughout the skeleton and known biology of all Late Miocene hominids. Rather than rejecting the hominid status of *Sivapithecus* and other Late Miocene hominids because not all of their postcranial morphology is strictly hominid or even extant hominoid-like, it is much more likely that these few characters reflect mosaic evolution of the hominid skeleton, uniquely derived features of the anatomy of *Sivapithecus*, as well as some parallelism in extant hominoids (Begun 1993; Begun et al. 1997; see below).

*Sivapithecus* postcrania, though they have been the subject of more discussions related to phylogeny, are actually less well known than *Proconsul*, *Equatorius*, or *Nacholapithecus*. The following is summarized mainly from Rose (1997), Richmond and Whalen (2001), and Madar et al. (2002). Much more information is available from all the references cited earlier. Two species of *Sivapithecus* are known from the humerus, which is unlike that of modern hominoids in the curvature of the shaft and the development of the deltopectoral plane. The bicipital groove is also broad and flat and suggests a posteriorly oriented humeral head, as in the Early and Middle Miocene Hominidea described earlier. However, the humerus has such an unusual morphology that the orientation of the head,
which is already somewhat difficult to predict from bicipital groove position (Larson 1996), cannot be reconstructed with great confidence. Nevertheless, the morphology of the proximal humerus in *Sivapithecus* is suggestive of some form of pronograde quadrupedalism as seen, for example, in extant cercopithecoids. If the humeral head were oriented more posteriorly, it would also be consistent with a scapula that is placed on the side of a compressed rib cage, as in typical mammalian quadrupeds, and unlike extant hominoids (Rose 1989; Ward 1997). No direct evidence is available for the thorax or any part of the axial skeleton of *Sivapithecus*, however, so this will also have to await further discoveries. The deltopectoral plane and the curvature of the shaft of the humeri in *Sivapithecus* are quite strongly developed compared to most cercopithecoids and indicate in my view a unique form of positional behavior that is neither extant hominoid nor extant cercopithecoid-like (Madar, et al. 2002). The distal end of the humerus is in the main hominoid-like, including a well-developed trochlea separated from the capitulum by a deep, well-defined groove (the zona conoidea), though in a few details of the posterior surface there are similarities to *Proconsul* and *Kenyapithecus* (Rose 1997). Overall, however, the functional morphology of the elbow of *Sivapithecus* is most like the hominoid elbow in its ability to resist movements other than flexion and extension at the elbow joint, a hallmark of the Hominidea (Rose 1988).

The *Sivapithecus* forearm is poorly known, especially the proximal portions of the ulna and radius, which would help to more fully understand the *Sivapithecus* elbow. A juvenile radial shaft is known that is described as *Proconsul*-like, though as a juvenile it is not clear to what extent any hominoid-like characters, such as curvature and the nature of the ligamentous/muscular insertions, would be expressed. On the other hand, the few carpal bones that are known show a mixture of hominoid and non-hominoid features. The capitate of *Sivapithecus* has a somewhat expanded and rounded head, as in great apes, but overall is transversely narrow and elongated proximodistally compared to great apes. The joint surface for the third metacarpal is irregular as in great apes. The hamate is similar in length/breadth proportions and has a less strongly projecting hamulus than do great ape hamates (Spoor et al. 1991). The joint on the hamate for the triquetrum is oriented as in gorillas and also most other nonhominoid anthropoids, and its shape suggests a stabilizing function at the wrist, which differs fundamentally from the typical mobility of the ulnar side of the wrist in extant hominoids. The proximal end of a first metacarpal is similar in morphology to hominids and Early Miocene Hominidea in being saddle shaped, a configuration considered to represent a good compromise between mobility and stability in a wide variety of positions. The manual phalanges are long and curved, with strongly developed ridges for the flexor muscles and their sheaths.
One complete phalanx has a relatively deep and somewhat dorsally positioned articular surface for the metacarpal head, which is more typical of palmigrade quadrupeds. However, it is not completely clear if this is from a hand or a foot, and if the latter is the case, a similar morphology exists in some hominoids as well.

The hindlimb of *Sivapithecus* is less well known but generally more similar to extant hominoids than the forelimb. The femur is known from proximal and distal ends but not from the same individual (Rose 1986; Madar et al. 2002). The hip joint as represented by the femoral head and neck was mobile in many directions, though it has a well-developed fovea capitis, unlike *Pongo*, which is highly distinctive (but not unique) in lacking a ligamentum teres of the femur and thus its attachment site to the femur, the fovea capitis. The distal end of the femur preserves evidence of a knee joint that is consistent with this interpretation, implying a knee joint loaded in positions away from the sagittal plane. The knee also has a number of features allowing for rotation of the leg and foot to adjust the lower extremity to a variety of positions close to and further away from the center of mass (Madar et al. 2002). In all of these features, the femur is more like that of hominoids than other anthropoids.

Other hindlimb elements include several tarsal bones, phalanges, and a well-preserved hallucial skeleton (Conroy and Rose 1983; Rose 1984, 1986, 1994). The tarsals are perhaps more like those of great apes than any other part of the post-cranium of *Sivapithecus* (Rose 1984; Madar et al. 2002), indicating the presence of a broad foot, able to assume many positions but stable in all of them, and supportive of body mass loading from many directions. The hallux or big toe is strikingly robust, much more so than in *Pongo*, and indicates a strongly developed grasping capability in the foot. The phalanges are also by and large hominoid-like, with well-developed features related to powerful flexion of the toes, a critical function in antipronograde activities (climbing as well as suspension).

### 4.5.2.3 *Sivapithecus* phylogeny and paleobiology

Overall, the morphology of *Sivapithecus* strongly supports a close phylogenetic relationship to *Pongo* but an adaptation that differed from *Pongo* in important aspects. Microwear suggests that *Sivapithecus* had a diet that was similar to that of chimpanzees while gnathic morphology suggests more of a hard object diet (Teaford and Walker 1984; Kay and Ungar 1997). Perhaps this reflects a capacity to exploit fallback or “keystone” resources in times of scarcity. Most hominoids are known to practice this strategy (Tutin and Fernandez 1993; Tutin et al. 1997). The case of gorillas may be most relevant to the question of the diet of *Sivapithecus*. 
Most gorillas have diets similar to chimpanzees but are able to exploit terrestrial herbaceous vegetation (THV) in lean seasons when soft fruit is less available or in contexts in which they are sympatric with chimpanzees (Tutin and Fernandez 1993; Tutin et al. 1997). The microwear results may reflect the preferred and most common components of the diet, while the morphology of the jaws and teeth may reflect a critical adaptation to a keystone resource on which survival would depend during stressful periods.

Postcranial evidence clearly indicates that *Sivapithecus* was not orang-‐like in its positional behavior. In fact, it was unique; there are probably no living analogues. *Sivapithecus* combines clear indications of pronograde forelimb postures and a palmigrade hand position with more antipronograde activities such as vertical climbing and clambering implied by elbow joint stability over a wide range of flexion/extension, powerful grasping hands and feet, an especially powerful hallux, and hindlimbs capable of wider ranges of joint excursions than in extant pronograde quadrupeds (Madar et al. 2002). It is difficult to imagine exactly what the positional behavior of *Sivapithecus* might have been like.

One constant in the postcranial functional morphology of *Sivapithecus* is arboreality. Perhaps *Sivapithecus* used its powerful limbs in climbing and bridging or clambering activities, spreading the limbs across multiple supports to access smaller branches. In a sense it is orang-‐like without the suspension. While *Sivapithecus* managed to distribute its considerable body mass across the tops of several branches, orangs do the same but from below. The advantage to suspension is added stability on horizontal supports in large animals, which otherwise need to generate very high levels of torque to stay atop a branch (Grand 1972, 1978; Cartmill 1985). Orang males are larger than *Sivapithecus* and may be beyond the threshold where pronograde limb postures are possible in the trees. The fact that the proximal half of the humerus of *Sivapithecus*, while similar to that of a pronograde quadruped, is exceptionally robust, with extremely well-‐developed shoulder muscle attachments, may be an indication of a unique approach to this problem.

*Sivapithecus* does share numerous postcranial features, especially of the elbow and hindlimb, with extant hominoids and *Dryopithecus*. It is therefore possible that the more monkey-‐like morphology of the proximal humerus and portions of the hands and feet are actually homoplasies with cercopithecoids caused by the adoption of more pronograde postures in a hominoid that evolved from a more suspensory ancestor (Begun et al. 1997). This requires many fewer homoplasies than the alternative hypothesis that all extant hominoid characters in all Late Miocene hominoids are homoplasies (Pilbeam 1996, 1997; McCrossin and Benefit 1997; Pilbeam and Young 2001, 2004). There is some evidence from the functional morphology of *Sivapithecus* to support the hypothesis that its
form of pronograde arboreal quadrupedalism is actually superimposed on a suspensory hominoid groundplan.

The problem of angular momentum causing instability in a large mammal standing on top of a branch is alleviated in part by spreading the limbs apart on a wide support or across several supports, which *Sivapithecus* seems to have been capable of doing (Madar et al. 2002). It can also be all alleviated by placing the center of mass closer to the support, which is suggested for *Griphopithecus* (Begun 1992a), and may have also occurred in *Sivapithecus*, as a consequence of its habitually more laterally placed limbs (Madar et al. 2002). The positioning of the limbs more laterally in hominoids is part of the suite of characters related to trunk morphology and scapular position. It is not facilitated by monkey-like trunks and scapular positions, which promote more parasagittal limb movements. Finally, an important response to angular momentum is to increase the torque generated by the limbs on the support, to prevent excessive excursions from a balanced position, especially when a single support of only modest size is used, again suggested to be an aspect of the positional behavior of *Sivapithecus* (Madar et al. 2002). Higher torque results from more powerful gripping, also characteristic of *Sivapithecus* (Madar et al. 2002), and may have been boosted by especially powerfully developed shoulder joint adduction and medial rotation, particularly if the shoulder is in a relatively abducted position to begin with, as in hominoids.

The morphology of the proximal half of the humerus in *Sivapithecus* is consistent with very powerful adduction and medial rotation by deltoideus and pectoralis major. These muscles left extremely prominent scars on the humerus of *Sivapithecus*. If the arm of *Sivapithecus* were positioned as in extant hominoids, laterally on a posteriorly positioned scapula, the adduction and medial rotation capacities of deltoideus and pectoralis would be increased by increasing the relative mass of the clavicular portion of deltoideus, which is unknown in *Sivapithecus*. However, in addition to the need for powerful muscles, which existed in *Sivapithecus*, these functions would also be enhanced by other attributes known in *Sivapithecus*. The extension of the muscles along the shaft distally and the possible decreased humeral neck torsion would increase the moment arm for these muscles in adduction and reposition the insertions of these muscles medially, possibly to make more of the deltoideus available for adduction and medial rotation. The strong mediolateral curvature of the shaft may result from high mediolateral bending stresses that would result from very powerful shoulder adduction on a fixed limb. The proximal shaft is also very broad mediolaterally, suggestive of strong mediolaterally directed stresses. While speculative, it is certainly conceivable that the upper part of the forelimb of *Sivapithecus* was less monkey-like than generally perceived and may not imply that much of the trunk
was of the primitive anthropoid type. A small number of autapomorphies of the shoulder of *Sivapithecus* may have allowed this taxon to practice a relatively efficient form of arboreal pronograde quadrupedalism while maintaining the capacity for many of the antipronograde activities of hominoids, though probably not frequent upper limb below branch suspension. This hypothesis is functionally consistent with the morphology of the *Sivapithecus* postcranial in general and is certainly more parsimonious than the hypothesis that would interpret all Late Miocene hominoid characters as homoplasies.

### 4.5.3 *Ankarapithecus*

Aside from some material from Nepal attributed to *Sivapithecus* (Munthe et al. 1983), *Sivapithecus* is known only from India and Pakistan. Specimens from central Anatolia, Turkey, once attributed to *Sivapithecus* (Andrews and Tekkaya 1980) are now assigned to *Ankarapithecus*, following the original conclusions of Ozansoy (1957, 1965). *Ankarapithecus meteai* is known from a male palate and mandible from two different individuals and a female partial skull (mandible and face) from a third locality, all close to each other in location and geologic time (Kappelman et al. 2003a). Begun and Güleç (1995, 1998) resurrected the nomen *Ankarapithecus* based mainly on the morphology of the premaxilla and the relationship between this bone and the maxilla but concluded that *Ankarapithecus* is nonetheless in the pongine clade. Alpagut et al. (1996) and Kappelman et al. (2003) described newer and much more complete fossils of *Ankarapithecus* and concluded that it is a stem hominid (sharing a common ancestor with both pongines and hominines). The new fossils discovered and described by these authors include the region around the orbits, which lacks some of the characters of *Sivapithecus*. The interorbital region is intermediate in breadth between *Pongo*, with the narrowest interorbitals, and African apes and the orbits themselves are broad rather than tall and narrow. Alpagut et al. (1996) and Kappelman et al. (2003) also interpret the supraorbital region as a supraorbital torus, characteristic of African apes and humans and some European Late Miocene taxa, and they interpret a frontal sinus in the cranium of *Ankarapithecus* as a frontoethmoidal sinus. These authors see the mixture of hominine and pongine characters as an indication that *Ankarapithecus* precedes their divergence.

#### 4.5.3.1 Craniodental evidence

The frontal sinuses in *Ankarapithecus* appear to be confined to the frontal squama and do not invade the frontal supraorbital region from a broad expansion of the
Ethmoidal sinuses. They are positioned and developed as in extant taxa with frontal pneumatizations derived either from the sphenoidal or maxillary sinuses and are unlike those derived from the ethmoid (see above discussion). The frontal pneumatization in *Ankarapithecus* is unlikely to be a frontoethmoid sinus and thus is not a synapomorphy of the hominines. The supraorbital region, while robust, is morphologically similar to the robust supraorbital costae of large orangs or *Cebus* and also unlike the bar-like supraorbital tori of African apes. Thus, the supraorbital region of the *Ankarapithecus* cranium is more pongine than hominine-like and, like the maxilla, probably represents the primitive morphology for the pongines (see below).

In *Ankarapithecus* the premaxilla, the portion of the palate with the alveoli for the incisors and the mesial half of the canines, is unlike that of *Sivapithecus* and more like that of African apes. The premaxilla is long, but it does not overlap the palatine process of the maxilla to fill the incisive fossa to the degree seen in *Sivapithecus*. Instead, the subnasal fossa is stepped (there is a drop between the base of the nasal aperture and the floor of the nasal cavity) into an incisive fossa that is most like that of some chimpanzees, a relatively large depression opening into a canal (the incisive canal that runs between the premaxilla and maxilla to exit on the palatal side via the incisive foramen). *Dryopithecus* has a similar configuration of the subnasal fossa, incisive canal and incisive foramen, though the fossa is larger and the canal is shorter in length and larger in caliber, as in some gorillas (Begun 1994a) (Figure 4.3). The premaxilla of *Ankarapithecus* is curved or convex anteroposteriorly as in *Sivapithecus*, African apes, and *Dryopithecus* but it is also convex transversely, as in African apes and *Dryopithecus* unlike *Sivapithecus*, which has a transversely flatter premaxilla. In all of these features, *Ankarapithecus* expresses a condition intermediate between pongines and hominines, which I consider primitive for the pongines (Begun and Güleç 1998). Alpagut et al. (1996) and Kappelman et al. (2003b) have suggested that these characters indicate that *Ankarapithecus* precedes the divergence of pongines and hominines. Other features of the morphology of *Ankarapithecus* resemble pongines more clearly, including canine implantation, zygoma size and orientation, orbital margin morphology, nasal length, and dental morphology. Overall, *Ankarapithecus* most closely resembles *Sivapithecus* and *Pongo* but retains a more primitive palatal morphology that suggests it is at the base of the pongine clade.

### 4.5.3.2 Postcranial evidence

Some postcrania of *Ankarapithecus* are known, including a well-preserved radius and two phalanges (Kappelman et al. 2003). A femur tentatively identified as
primate is more likely in my opinion to be from a carnivore. The radius shares characters with extant great apes including features of the radial head and comparatively long radial neck (Kappelman et al. 2003). Other hominoid-like features described or figured in Kappelman et al. (2003) but not identified as hominoid-like by these authors include a proximodistally compressed and more circular radial head, a deep radial fovea, flat as opposed to concave shaft surface along the anterior surface, a more distal origin of the interrosseus crest, and a smooth distal dorsal surface. The specimen actually strikes me as quite hominoid-like with a few features more normally associated with large nonhominoid anthropoids, a pattern more or less in keeping with other Late Miocene hominoids. The phalanges are said to be relatively straight and thus non-hominoid-like, but only distal portions are preserved. They too strike me as more hominoid-like than Kappelman et al. (2003) suggest, given its distal shaft robusticity, dorso-palmar compression, and distopalmarly projected condyles. The curvature and ridges for the flexor musculature are said to be poorly developed compared to hominoids, but this may be related to many factors (preservation, age, digit attribution).

Overall, *Ankarapithecus* is characterized by many features found in other pongines and is probably the most basal known member of that clade. Like *Sivapithecus*, it was much more massive in the development of its masticatory apparatus than *Pongo*, and its postcranium, though very poorly known, suggests arboreality and at least some features of hominoid-like antipronograde positional behaviors, but probably lacking the degree of suspension seen in *Dryopithecus*, *Oreopithecus*, and extant hominoids (but see Kappelman et al. 2003).

4.5.4 Other probable fossil pongines

4.5.4.1 *Gigantopithecus*

Extremely large fossil hominoids, larger than any extant primate, have been known from Asia since the early part of the twentieth century. *Gigantopithecus blacki* (Koenigswald 1935) is a Pleistocene taxon known from numerous isolated teeth and a few mandibles. It is recent enough to be outside the purview of this review and has been described many times elsewhere. *Gigantopithecus giganteus* (Pilgrim 1915) is a Late Miocene possible member of this genus known from a lower molar and mandible from the Late Miocene of the Siwaliks that are mainly distinguished from *Sivapithecus* by size. They are larger than any *Sivapithecus* and the only known mandible is distinctive in having reduced anterior tooth crown heights and molarized or enlarged premolars. *G. blacki*, on the other hand, is
larger still and has highly complicated postcanine occlusal morphology and relatively even larger mandibles and smaller anterior teeth. Because *G. giganteus* and *G. blacki* share characters of the lower jaws and teeth that appear commonly during the course of hominoid evolution (in fact, in many other mammal lineages as well), the relationship between the two is uncertain. Jaws and teeth in general, and mandibles in particular, are magnets for homoplasy in primate evolution (Begun 1994b), and this may be another example. However, the most parsimonious hypothesis is that *G. giganteus* is a primitive member of the *Gigantopithecus* clade and that the strong similarity to *Sivapithecus* in the molars, apart from size, suggests that it is the sister clade to that taxon. If a better ancestor for *Gigantopithecus blacki* turns up, the nomen *Indopithecus* is available for *G. giganteus* (Table 4.1).

### 4.5.4.2 Lufengpithecus

Thousands of fossils, mostly isolated teeth, are known from a number of localities in Yunnan province, southern China. These are attributed to the genus *Lufengpithecus* (Wu 1987), widely believed to be a pongine. Kelley tentatively recognizes three species of *Lufengpithecus*, distinguished mainly by size and geography (each is known from a single site). *Lufengpithecus* shares a few cranial characters with other pongines including a small, pear-shaped nasal fossa, aspects of the implantation of the canine roots in the maxilla, a deep canine fossa, supraorbital costae, and anteriorly oriented zygoma (Schwartz 1997 and personal observations). However, while it lacks many of the detailed similarities of the face between *Sivapithecus* and *Pongo*, its teeth are much more like those of *Pongo* than *Sivapithecus* in details of occlusal morphology, including the unusual presence of highly complex wrinkling or crenulations (Kelley 2002). The face of *Lufengpithecus* is unlike those of *Sivapithecus* and *Pongo* in having broad orbits, a broad interorbital space, a comparatively short premaxilla, high crowned incisors and canines, compressed and very tall crowned male lower canines. Though very damaged, my impression is that the nasal floor is unlike the smooth floor of *Sivapithecus* and *Pongo* but possibly more similar to the morphology in *Ankarapithecus*.

* L. *lufengensis* (Xu et al. 1978) from a site near Shihuiiba, in Lufeng county, is the best-known species of the genus and is also known from a number of postcranial remains including fragments of a scapula, clavicle, radius, first metatarsal, and two phalanges. None have been published in detail, but all of these specimens show clear indications of modern hominid morphology associated with suspensory positional behaviors (personal observations). This is especially true of the phalanges, which are strongly curved and bear the markings of
powerful flexor tendons. The metatarsal is similar to that of *Sivapithecus* in its relative robusticity.

Until the fossils attributed to *Lufengpithecus* are published in detail, it will be impossible to be confident in assessing their taxonomic and phylogenetic relations. At this point, it seems likely that *Lufengpithecus* is a pongine and probably a sister taxon to the *Pongo–Sivapithecus–Ankarapithecus* clade. However, the generally more *Pongo*-like morphology of the molar occlusal surfaces and the more clearly hominoid-like morphology of the postcrania are enigmatic and suggest caution in interpreting evolutionary relationships.

### 4.5.4.3 *Khoratpithecus*

Two samples of East Asian Miocene hominoids have recently come to light. Chaimanee et al. (2003) describe a Middle Miocene sample of hominoids from Thailand they originally attributed to a species of *Lufengpithecus*. The age of the locality is not completely certain, and it is possible that the fauna could be correlated with a more recent magnetostratigraphic interval, but for now the sample is considered to date to the late Middle Miocene or early Late Miocene. However, on the basis of more recently discovered Late Miocene hominoid fossils from Thailand, Chaimanee et al. (2004) described a new genus, *Khoratpithecus*, and revised their previous taxonomic conclusions to include the Middle Miocene taxon in the newly named genus as well. The fossils, a sample of isolated teeth and a well-preserved mandible, are very similar to *Lufengpithecus* but show a number of differences in the anterior dentition and lower jaw (Chaimanee et al. 2004). Chaimanee et al. (2004) interpret *Khoratpithecus* to be more closely related to *Pongo* than is any other pongine, mainly based on the shared derived character of a missing anterior digastric muscle. More fossils are needed to test this hypothesis more fully. The greater significance of these discoveries is the location, in Thailand, and the possibly early age, Middle Miocene.

### 4.5.5 Fossil hominines

At about the same time that hominids appear in Asia, they make their first appearance in Europe. As is the case with the earliest pongines, the earliest hominines lack a number of synapomorphies of living hominines (African apes and humans) and are less distinct from related non-hominines than are more recently evolved hominines. This has led naturally to differences of opinion
regarding the systematics of this group. There are three main interpretations of the evolutionary relations among the taxa included here in the Homininae. As noted, some researchers conclude that no known Eurasian Late Miocene taxon has a specific relationship to extant hominoids (Pilbeam 1996, 1997; McCrossin and Benefit 1997; Pilbeam and Young 2001, 2004). Most researchers, however, accept the hominid status of these fossil taxa but are divided as to their inter-relationships. Some researchers (Andrews 1992) have concluded that European Late Miocene hominids are best viewed as stem hominids, preceding the divergence of hominines and pongines. Others interpret most or all Eurasian hominines to be members of the pongine clade (Moya-Sola et al. 1995). Finally, some researchers interpret most or all European hominids to be hominines, although there is disagreement among them as to the precise pattern of relations (Bonis and Koufos 1997; Begun and Kordos 1997). As my interpretation falls with the last group, this will be reflected in this chapter. I will however attempt to outline the major arguments from each perspective.

4.5.6 Pierolapithecus

The oldest known genus of hominine is the recently described partial skeleton of *Pierolapithecus* (Moya-Solà et al. 2004). The specimen, from northern Spain, is dated to about 13 Ma based on biostratigraphic evidence (Moya-Solà et al. 2004). The specimen includes most of a face which, though badly distorted, preserves nearly all the teeth and many informative facial characters. It also includes a partial postcranial skeleton, the most informative parts of which are some lumbar vertebrae, ribs, and a number of hand and foot bones. Moyà-Solà et al. (2004) interpret *Pierolapithecus* to be a basal or stem hominid. They cite the lumbar vertebrae, which preserve evidence of a hominoid-like vertebral column and by extension rib cage. This is indicated by the position of the lumbar transverse processes, placed more posteriorly in hominoids to stiffen the lower back (Ward 1993). However, the morphology of the lumbar vertebrae in *Pierolapithecus* is more hylobatid-like, extant hominids having even more posteriorly positioned transverse processes. Other aspects of the postcranium that clearly support the hominoid status of *Pierolapithecus* include ribs indicative of a broad, anteroposteriorly compressed rib cage, robust clavicle, and a wrist morphology indicating no direct contact between the carpus at the triquetrum and the ulna (Moyà-Solà et al. 2004). These features are shared with all extant hominoids, though hylobatids are somewhat intermediate in carpal/ulnar contact between non-hominoid anthropoids with direct contact and hominoids with a large intervening articular meniscus (Lewis 1989).
